

Macroeconomia Dinâmica

Notas de aula

Antônio Morales

April 21, 2026

Prefácio

Estas notas de aula foram elaboradas para as disciplinas de Macroeconomia III da Belavista e para a eletiva de Macroeconomia Dinâmica do Insper. A ideia da montagem deste curso foi ser uma adaptação "suave" entre o conteúdo de macroeconomia da graduação e dos cursos de mestrado/doutorado. Principalmente, dar uma roupagem mais moderna do que se faz hoje em macroeconomia em termos de microfundamentos. O texto será apresentado em inglês já que as aulas da Belavista também são neste idioma.

As notas são baseadas fortemente em diversos livros mais completos como [3], [4], [5], e [7].

Agradeço enormemente ao João Meningue, meu monitor na Belavista na primeira vez que dei o curso. O início deste projeto não seria possível sem você.

1 Introduction

These notes provide a structured overview of the main topics covered in Dynamical Macroeconomics, focusing on dynamic macroeconomic models and intertemporal decision-making. The material is based primarily on [4], but also draws on complementary references, such as [7], whenever additional perspectives or formal developments are useful.

These notes starts by introducing intertemporal consumption and saving decisions, highlighting how households allocate resources over time in response to income, interest rates, and preferences.

This framework provides the foundation for more advanced dynamic models used throughout modern macroeconomics. Building on this intuition, the notes then present the overlapping-generations (OLG) model, which departs from the representative-agent framework and allows the analysis of demographic structure, capital accumulation, and public policies such as pension systems.

Subsequent sections focus on labor supply decisions and the labor–leisure trade-off, both in static and dynamic settings. These models clarify how wages, taxes, and transfers affect individual labor supply choices and aggregate labor market outcomes. The notes then turn to investment decisions, discussing present value, risk, Tobin’s Q , and adjustment costs, which together explain how firms decide how much to invest in the presence of uncertainty and intertemporal trade-offs.

The general equilibrium framework integrates households’ consumption–saving and labor–leisure choices with firms’ production and investment decisions, allowing for a coherent analysis of how prices coordinate economic activity across markets and over time. Finally, the notes introduce the tools of optimal control and dynamic programming, which are essential for solving infinite-horizon macroeconomic models and for analyzing the dynamics of capital accumulation, consumption, and policy interventions.

Overall, the objective of these notes is to provide an accessible and coherent roadmap to the core theoretical models of modern macroeconomics, highlighting their economic intuition while maintaining the formal structure necessary for analytical and quantitative applications.

2 Consumption and Savings Model

2.1 The Keynesian View of Consumption

Keynes' point of view on consumption in Kurlat's book is characterized by the marginal propensity to consume, that is, the share of the economy's production consumed by those who compose it.

$$C = c(Y) \quad (2.1)$$

where C is total consumed, Y the the output of the economy and c is the proportion of Y that will be consumed. Keynes stated that, when Y grows, C also grows, but in a minor way. Mathematically, he said, $c'(Y) < 1$, or that the elasticity of consumption with respect to income is positive but less than 1. Mathematically:

$$\frac{c'(Y)Y}{c(Y)} = \frac{\partial \log(c(Y))}{\partial \log(Y)} < 1 \quad (2.2)$$

2.2 A Two-Period Model of Consumption

Consider an economy composed of one family and two periods, t_1 and t_2 . The utility function of this family (or this economy) is:

$$U(c_1, c_2) = u(c_1) + \beta u(c_2), \quad (2.3)$$

where c_1 and c_2 are the consumption of this family in periods 1 and 2, respectively. β is just a number that demonstrates that the family prefers consumption in t instead of $t + 1$; they are impatient. The saving is:

$$a = y_1 - c_1 \quad (2.4)$$

a in the second period will be boosted by the real interest rate r . This way,

$$c_2 = y_2 + (1 + r)a \quad (2.5)$$

rearranging,

$$c_1 + \frac{1}{1+r}c_2 = y_1 + \frac{1}{1+r}y_2 \quad (2.6)$$

Note that $\frac{1}{1+r}$ represents the value of c_2 and y_2 in period t ; thus, one can conclude that the interest rate indicates how much the market pays in terms of c_2 consumption for less consumption in c_1 . Therefore, a high interest rate means a higher cost of consumption in the first period. Still at this point, the income of the family in two periods is represented by $y_1 + \frac{1}{1+r}y_2$, which means the present value of all income ¹.

Analyzing the consumer optimization problem:

$$\begin{aligned} \max_{c_1, c_2} \quad & u(c_1) + \beta u(c_2) \\ \text{s.t.} \quad & c_1 + \frac{1}{1+r}c_2 \leq y_1 + \frac{1}{1+r}y_2 \end{aligned} \quad (2.7)$$

¹Making explicit, $\frac{1}{1+r}$ works showing the value of futures consumption or income in the current period.

This problem will look for the point at the budget constraint curve where the indifference curve of the trade between c_1 and c_2 is tangential to the budget constraint curve, as is shown in the following figure:

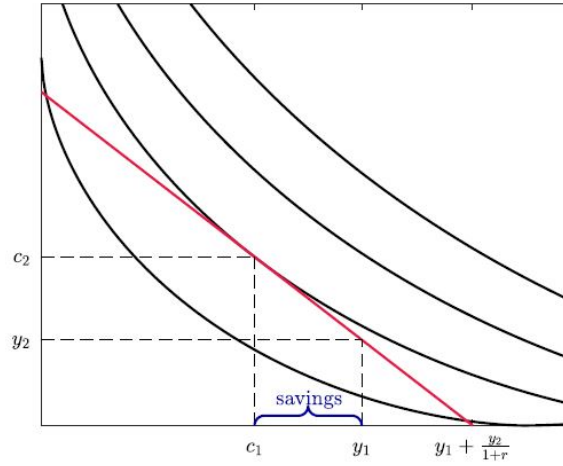

Figure 1: Kurlat (2020)

Using the *Lagrangian* allows one to find the solution of the maximization through the first-order conditions.

$$\begin{aligned}\mathfrak{L}(c_1, c_2, \lambda) &= u(c_1) + \beta u(c_2) - \lambda \left[c_1 + \frac{1}{1+r} c_2 - y_1 - \frac{1}{1+r} y_2 \right] \\ \frac{\partial \mathfrak{L}}{\partial c_1} &= u'(c_1) - \lambda = 0 \\ \frac{\partial \mathfrak{L}}{\partial c_2} &= \beta u'(c_2) - \frac{\lambda}{1+r} = 0\end{aligned}$$

Rearranging,

$$u'(c_1) = \beta(1+r)u'(c_2) \quad (2.8)$$

Equation (2.8) is the *Euler equation*. Note that this informs the trade-off that the household faces between changing consumption in the first period and consumption in the second period. If the consumption of one unit happens in the first period, there will be $u'(c_1)$ units of utility (left hand side of (2.8)).

However, suppose the family chooses in the second period. In that case, they will obtain $(1+r)$ units of the same consumption in the future (interest rate), which means $u'(c_2)$ marginal utility multiplied by β for the household's impatience. The maximization occurs when (2.8) holds. It is important to note that the household can obtain either positive or negative savings in the first period, depending on its preferences, price, or interest rate. The household aims to smooth its consumption.

2.2.1 The Effect of Interest Rate

At this point, it is perceptible that this model is very similar to consumer theory in microeconomics. Therefore, it is important to examine the substitution effect and the income effect that are at play.

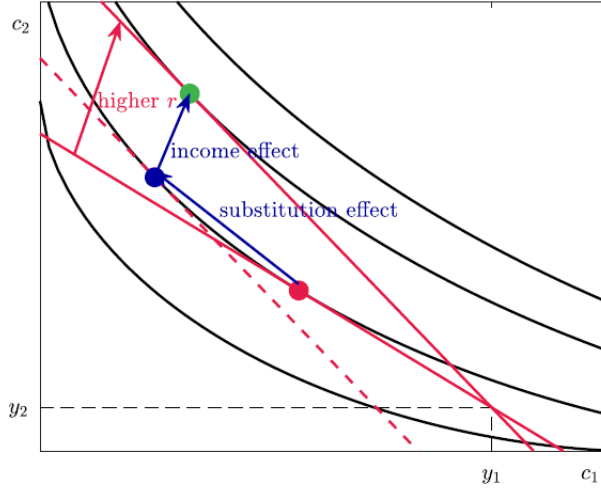

Figure 2: Kurlat (2020)

Note that when the interest rate increases, there will be a new slope in the budget constraint curve. As a consequence, a new c_1, c_2 indifference curve will be tangented, and a new composition of c_1 and c_2 will be chosen. A part of this choice is the consequence of the substitution effect, and another is the income effect, as 2 shows.

The direction of the effects depends on the household's preferences regarding positive or negative savings. If the family has negative savings, the increase in interest rate will have a negative impact on the family's consumption, which means a lower indifference curve of c_1, c_2 .

2.2.2 An Explicit Example

Assume the utility function is a CRRA, that is:

$$u(c) = \frac{c^{1-\sigma}}{1-\sigma} \quad (2.9)$$

The derivative is:

$$u'(c) = c^{-\sigma} \quad (2.10)$$

remembering (2.8), that is, $u'(c_1) = \beta(1+r)u'(c_2)$. Applying (2.10) into (2.8), results in

$$\begin{aligned} c_1^{-\sigma} &= \beta(1+r)c_2^{-\sigma} \\ \Rightarrow c_2 &= [\beta(1+r)]^{\frac{1}{\sigma}} c_1 \end{aligned} \quad (2.11)$$

using the budget restriction, $c_1 + \frac{1}{1+r}c_2 = y_1 + \frac{1}{1+r}y_2$, and applying (2.11),

$$c_1 + \frac{1}{1+r}[\beta(1+r)]^{\frac{1}{\sigma}} c_1 = y_1 + \frac{1}{1+r}y_2 \quad (2.12)$$

As a result, the optimal consumption of c_1 is given by:

$$c_1 = \frac{y_1 + \frac{1}{1+r}y_2}{1 + \beta^{\frac{1}{\sigma}}(1+r)^{\frac{1}{\sigma}-1}} \quad (2.13)$$

Note that c_1 optimal is expressed in terms of income in present value $y_1 + \frac{1}{1+r}y_2$ and the impatience of the family $1 + \beta^{\frac{1}{\sigma}}(1+r)^{\frac{1}{\sigma}-1}$.

2.3 Extension to Many Periods

Sometimes it could be necessary to analyze the problem of consumption for more than two periods. To make it, the simple model's principles are used. Thus, the preferences of the household is now:

$$\sum_{t=0}^T \beta^t u(c_t) \quad (2.14)$$

Note that the consumption of futures periods affects the utility, but the more distant this consumption is, the less impact it has on utility at time t , since $\beta < 1$. Consider $T = \infty$ as an assumption. Once that a_t represents the savings of the household in time t , a_{t+1} is expressed by:

$$a_{t+1} = (1 + r)a_t + y_t - c_t \quad (2.15)$$

If $T = \infty$, the family will face infinite constraints that relate two consecutive periods like 2.15. To solve the maximization problem, a simple constraint is necessary, which can be achieved by substituting one term for another with the savings, that is,

$$a_1 = y_0 - c_0 + (1 + r)a_0 \quad (2.16)$$

$$a_2 = y_1 - c_1 + (1 + r)a_1 \quad (2.17)$$

It is possible to substitute a_1 expression at a_2 expression,

$$a_2 = y_1 - c_1 + (1 + r)[y_0 - c_0 + (1 + r)a_0] \quad (2.18)$$

For a_3 ,

$$\begin{aligned} a_3 &= y_2 - c_2 + (1 + r)[y_1 - c_1 + (1 + r)[y_0 - c_0 + (1 + r)a_0]] \\ a_3 &= y_2 - c_2 + (1 + r)(y_1 - c_1) + (1 + r)^2(y_0 - c_0) + (1 + r)^3a_0 \end{aligned} \quad (2.19)$$

For period- T , the constraint is:

$$a_{T+1} = \sum_{t=0}^T y_t(1 + r)^{T-t} - \sum_{t=0}^T c_t(1 + r)^{T-t} + (1 + r)^{T+1}a_0 \quad (2.20)$$

or

$$\frac{a_{T+1}}{(1 + r)^T} + \sum_{t=0}^T \frac{c_t}{(1 + r)^t} = \sum_{t=0}^T \frac{y_t}{(1 + r)^t} + (1 + r)a_0 \quad (2.21)$$

Equation (2.21) has much information; there is the present value for the consumption of all periods, $\frac{c_t}{(1+r)^t}$, present value for the income of all periods, $\frac{y_t}{(1+r)^t}$, the term $(1 + r)a_0$ is equals zero in two periods example because is assumed that $a_0 = 0$, and represents the value for all period of the savings that the household was born with. $\frac{a_{T+1}}{(1+r)^T}$ represents the present value of any savings that the household has after the final period. Note that if $\frac{a_{T+1}}{(1+r)^T} > 0$, it means that the household has left an inheritance; on the other hand, if this value is negative, there will be debt. To avoid an infinite debt, since this probably will be the optimal choice for the family that is looking for the maximum consumption, the *no-ponzi* condition is imposed, that is, for $T \rightarrow \infty$,

$$\lim_{t \rightarrow \infty} \frac{a_T}{(1+r)^T} \geq 0 \quad (2.22)$$

So, (2.21) becomes:

$$\sum_{t=0}^{\infty} \frac{c_t}{(1+r)^t} = \sum_{t=0}^{\infty} \frac{y_t}{(1+r)^t} + (1+r)a_0 \quad (2.23)$$

The new household's maximization problem is:

$$\begin{aligned} & \sum_{t=0}^T \beta^t u(c_t) \\ \text{s.t. } & \sum_{t=0}^T \frac{c_t}{(1+r)^t} = \sum_{t=0}^T \frac{y_t}{(1+r)^t} + (1+r)a_0 \end{aligned} \quad (2.24)$$

This way, the Lagrangian is:

$$L(c_0, c_1, \dots) = \sum_{t=0}^T \beta^t u(c_t) - \lambda \left[\sum_{t=0}^T \frac{c_t}{(1+r)^t} - \sum_{t=0}^T \frac{y_t}{(1+r)^t} - (1+r)a_0 \right] \quad (2.25)$$

The first order condition for two periods subsequent is:

$$\begin{aligned} \beta^t u'(c_t) - \lambda \frac{1}{(1+r)^t} &= 0 \\ \beta^{t+1} u'(c_{t+1}) - \lambda \frac{1}{(1+r)^{t+1}} &= 0 \end{aligned} \quad (2.26)$$

Rearranging,

$$u'(c_t) = \beta(1+r)u'(c_{t+1}) \quad (2.27)$$

(2.27) is the *Euler equation*, and the interpretation is the same as the case of two periods; that is, this informs the trade-off that the households face between changing consumption in the period t and consumption in the period $t+1$.

3 The Overlapping-Generations Model

This model is based on Chapter 6 from Wickens' book [7]. Now, there is no longer a representative-agent model, which has all firms and households as the same; instead, there will be two different kinds of people, the old and the young. Every person lives for two periods. This way, the young have to decide for two periods, while the old decide only for one period. The young work, while the old retire. So, the population at the period t for the Overlapping-Generations Model (OLG) is:

$$N_t = N_{1,t} + N_{2,t}, \quad (3.1)$$

where $N_{1,t}$ represents the young populations at period t , while $N_{2,t}$ indicates the old population. So, in the period t , the old generation is the young generation at period $t-1$. Therefore, $N_t = N_{1,t} + N_{1,t-1}$. Consider the growth of the population at the fixed rate n . Thus, $N_{1,t} = (1+n)N_{1,t-1}$

$$N_t = N_{1,t} + \frac{N_{1,t}}{(1+n)} \quad (3.2)$$

Since the consumption per capita for young and old are, respectively, $c_{1,t}$ and $c_{2,t}$ at time t , the consumption at time t could be expressed by:

$$C_{i,t} = c_{i,t}N_{i,t}, \quad i = 1, 2 \quad (3.3)$$

So, the total consumption could be indicated by²:

$$\begin{aligned} C_t &= C_{1,t} + C_{2,t} \\ &= \left(c_{1,t} + \frac{1}{1+n}c_{2,t} \right) N_{1,t} \end{aligned} \quad (3.4)$$

The income in this economy will be:

$$Y_t = C_t + I_t \quad (3.5)$$

I_t is the total invested at time t . There is depreciation of the capital, so the following equation describes the accumulation of capital:

$$\Delta K_{t+1} = I_t - \delta K_t, \quad (3.6)$$

This way, the resource constraint, at time t , could be indicated by:

$$Y_t = \left(c_{1,t} + \frac{1}{1+n}c_{2,t} \right) N_{1,t} + K_{t+1} - (1-\delta)K_t \quad (3.7)$$

or, in terms *per capita*, dividing by N_t , we get:

$$\begin{aligned} y_t &= \frac{N_{1,t}}{N_t} \left(c_{1,t} + \frac{1}{1+n}c_{2,t} \right) + \frac{N_{1,t}}{N_t} \frac{N_{1,t+1}}{N_{1,t}} \frac{K_{1,t+1}}{N_{t+1}} - (1-\delta) \frac{N_{1,t}}{N_t} \frac{K_t}{N_{1,t}} \\ y_t &= \frac{1}{1+(1/n)} \left[c_{1,t} + \frac{1}{1+n}c_{2,t} + (1+n)k_{t+1} - (1-\delta)k_t \right] \end{aligned}$$

²Note that $1/(1+n) \cdot N_{1,t}$ is the old population at period 2, as was shown by (3.2).

³ $k_t = K_t/N_t$

The production function is:

$$Y_t = F(K_t, N_{1,t}) \quad (3.8)$$

or,

$$\begin{aligned} y_t &= \frac{Y_t}{N_t} = \frac{N_{1,t}}{N_t} F\left(\frac{K_t}{N_{1,t}}, 1\right) \\ &= \frac{1}{1 + (1/n)} f(k_t), \end{aligned} \quad (3.9)$$

This way, the constraint *per capita* is:

$$f(k_t) = c_{1,t} + \frac{1}{1+n} c_{2,t} + (1+n)k_{t+1} - (1-\delta)k_t \quad (3.10)$$

The rate of return to capital, for the maximization of profit, is equal to the net marginal product of the capital:

$$r_t = f'(k_t) - \delta \quad (3.11)$$

Consider constant returns to scale; thus, the wage for the young, the only one who works in the economy, is:

$$w_t = f(k_t) - k_t f'(k_t) \quad (3.12)$$

Since the young do not work at $t+1$, they need savings at t to consume at $t+1$, so:

$$s_{1,t} = w_t - c_{1,t} \quad (3.13)$$

At time $t+1$, when they will be old, all income will be consumed, and this income will be equal to $(1+r_{t+1})s_{1,t}$. Thus, the intertemporal budget constraint is expressed as:

$$c_{1,t} + \frac{c_{2,t+1}}{1+r_{t+1}} = w_t. \quad (3.14)$$

From 3.6, is known that:

$$\begin{aligned} \Delta K_{t+1} &= Y_t - c_{1,t}N_{1,t} - c_{2,t}N_{1,t-1} - \delta K_t \\ &= w_t N_{1,t} + r_t K_t - c_{1,t}N_{1,t} - c_{2,t}N_{1,t-1}, \end{aligned} \quad (3.15)$$

since $c_{1,t} = w_t - s_t$ and $c_{2,t} = (1+r_t)s_t$

$$\begin{aligned} K_{t+1} - K_t &= w_t N_{1,t} + r_t K_t - (w_t - s_t)N_{1,t} - ((1+r_t)s_t)N_{1,t-1} \\ K_{t+1} - K_t &= w_t N_{1,t} + r_t K_t - w_t N_{1,t} + s_t N_{1,t} - (1+r_t)s_t N_{1,t-1} \\ K_{t+1} - K_t &= r_t K_t + s_t N_{1,t} - (1+r_t)s_{t-1}N_{1,t-1} \\ K_{t+1} &= K_t + r_t K_t + s_t N_{1,t} - (1+r_t)s_{t-1}N_{1,t-1} \\ K_{t+1} - s_t N_{1,t} &= K_t(1+r_t) - (1+r_t)s_{t-1}N_{1,t-1} \\ K_{t+1} - s_t N_{1,t} &= (1+r_t)[K_t - s_{t-1}N_{1,t-1}] \end{aligned}$$

This equation is stable only when:

$$K_{t+1} = s_t N_{1,t}, \quad (3.16)$$

That is, the demand for capital must be equal to the supply of savings. Rearranging 3.16,

$$s_t = \frac{K_{t+1}}{N_{1,t}} = (1+n)k_{t+1} \quad (3.17)$$

Plugging 3.17 into $c_{2,t+1} = (1+r_{t+1})(w_t - c_{1,t})$,

$$c_{2,t+1} = (1+r_{t+1})(1+n)k_{t+1} \quad (3.18)$$

Note that 3.18 indicates that the consumption for the old is related to the next period capital stock.

Consider that the preferences of both generations are the same and equal:

$$\mathcal{U} = u(c_{1,t}) + \beta u(c_{2,t+1}) \quad (3.19)$$

This way, the maximization problem is described by:

$$\begin{aligned} \max_{c_{1,t}, c_{2,t+1}} \quad & \mathcal{U} = u(c_{1,t}) + \beta u(c_{2,t+1}) \\ \text{s.t.} \quad & c_{2,t+1} = (1+r_{t+1})(w_t - c_{1,t}) \end{aligned} \quad (3.20)$$

This way, the Lagrangian is

$$\mathcal{L} = u(c_{1,t}) + \beta u(c_{2,t+1}) - \lambda[c_{2,t+1} - (1+r_{t+1})(w_t - c_{1,t})] \quad (3.21)$$

The F.O.C. are:

$$\begin{aligned} \lambda &= \frac{u'(c_{1,t})}{1+r_{t+1}} \\ \lambda &= \beta u'(c_{2,t}) \\ \therefore u'(c_{1,t}) &= \beta(1+r_{t+1})u'(c_{2,t}) \end{aligned} \quad (3.22)$$

which is the Euler equation for the Overlapping Generations Model.

Assume that $\beta = \frac{1}{1+\theta}$. Moreover, consider $u(c_{i,t}) = \frac{c_{i,t}^{1-\sigma}-1}{1-\sigma}$. Consequently, $u'(c_{i,t}) = c_{i,t}^{-\sigma}$. Thus,

$$c_{2,t+1} = \left(\frac{1+r_{t+1}}{1+\theta} \right)^{\frac{1}{\sigma}} c_{1,t} \quad (3.23)$$

Note that if the $r_{t+1} > \theta$, then the interest rate is bigger than the discount factor, i.e., the interest paid more than compensates the consumer for deferring consumption to a future period; consequently, $c_{1,t} < c_{2,t+1}$. The opposite relation is true.

3.1 Short-Run Dynamics and Long-Run Equilibrium

First of all, plugging 3.23 into 3.13, results in:

$$s_t = w_t - \left(\frac{1+r_{t+1}}{1+\theta} \right)^{-\frac{1}{\sigma}} c_{2,t+1}$$

using this results in 3.13, plugging this into 3.14 and rearranging,

$$\left[1 + \frac{(1+r_{t+1})^{1-\frac{1}{\sigma}}}{(1+\theta)^{-\frac{1}{\sigma}}} \right] c_{2,t+1} = (1+r_{t+1})w_t$$

Considering 3.13 and the restriction 3.14, could be represented by $c_{2,t+1} = (1+r_{t+1})(s_t)$,
or

$$\begin{aligned}
c_{2,t+1} &= (1+r_{t+1}) \left[w_t - \left(\frac{1+r_{t+1}}{1+\theta} \right)^{-\frac{1}{\sigma}} c_{2,t+1} \right] \\
c_{2,t+1} &= (1+r_{t+1})(w_t) - (1+r_{t+1}) \left(\frac{1+r_{t+1}}{1+\theta} \right)^{-\frac{1}{\sigma}} c_{2,t+1} \\
c_{2,t+1} + (1+r_{t+1}) \left(\frac{1+r_{t+1}}{1+\theta} \right)^{-\frac{1}{\sigma}} c_{2,t+1} &= (1+r_{t+1})(w_t) \\
c_{2,t+1} \left(1 + \frac{(1+r_{t+1})^{1-\frac{1}{\sigma}}}{(1+\theta)^{-\frac{1}{\sigma}}} \right) &= (1+r_{t+1})(w_t) \\
c_{2,t+1} &= \frac{(1+r_{t+1})(w_t)}{1 + \frac{(1+r_{t+1})^{1-\frac{1}{\sigma}}}{(1+\theta)^{-\frac{1}{\sigma}}}}
\end{aligned}$$

It is possible to plug this equation into use 3.12 and, then, use this into 3.18, then

$$\begin{aligned}
\frac{(1+r_{t+1})(f(k_t) - k_t f'(k_t))}{1 + \frac{(1+r_{t+1})^{1-\frac{1}{\sigma}}}{(1+\theta)^{-\frac{1}{\sigma}}}} &= (1+r_{t+1})(1+n)k_{t+1} \\
\frac{(f(k_t) - k_t f'(k_t))}{1 + \frac{(1+r_{t+1})^{1-\frac{1}{\sigma}}}{(1+\theta)^{-\frac{1}{\sigma}}}} &= (1+n)k_{t+1} \\
k_{t+1} &= \frac{(f(k_t) - k_t f'(k_t))}{\left\{ (1+n) \left[1 + \frac{(1+r_{t+1})^{1-\frac{1}{\sigma}}}{(1+\theta)^{-\frac{1}{\sigma}}} \right] \right\}}
\end{aligned} \tag{3.24}$$

A solution for 3.24 could be found with a logarithmic function of utility, which implies $\sigma = 1$ and, consequently, eliminates r_{t+1} . Assuming a Cobb-Douglas function means $f(k_t) = k_t^\alpha$ and $f'(k_t) = \alpha k_t^{-(1-\alpha)}$. This way,

$$\begin{aligned}
k_{t+1} &= \frac{1}{(1+n)(2+\theta)} [f(k_t) - k_t f'(k_t)] \\
k_{t+1} &= \phi k_t^\alpha,
\end{aligned} \tag{3.25}$$

where $\phi = (1-\alpha)/[(1+n)(2+\theta)]$. The stability of 3.25 depends on $-1 < \partial k_{t+1}/\partial k_t < 1$. Using 3.25 and assuming $k_{t+1} = k_t = k^*$ it is possible to find the value of k^* in the steady state, that is,

$$k^* = \left[\frac{1-\alpha}{(1+n)(2+\theta)} \right]^{\frac{1}{(1-\alpha)}} \tag{3.26}$$

The convergence around the fixed point k^* is expressed for the following equation:

$$\Delta k_{t+1} = -(1-\alpha)(k_t - k^*) \tag{3.27}$$

⁴. Also it is important to point out that around k^* , $\partial k_{t+1}/\partial k_t = \alpha < 1$. The following graph describes the convergence to the steady state or k^* . Before reading the graphic, it

⁴This equation is the result of a Taylor Expansion around the fixed point k^*

is important to consider 3.25. The straight line represents points where $k_{t+1} = k_t$, which happens in the steady state. Starting from point A, it must run vertically to the curve $k_{t+1} = \phi k_t$, which is concave, and find the value of k_{t+1} . Since the value of k_{t+1} was identified, one must run horizontally to the right and find the value of k_t that is the same as k_{t+1} . Thus, the process is repeated until point B is achieved, then the process stops since $k_{t+1} = k_t$ and there is no space to continue the process.

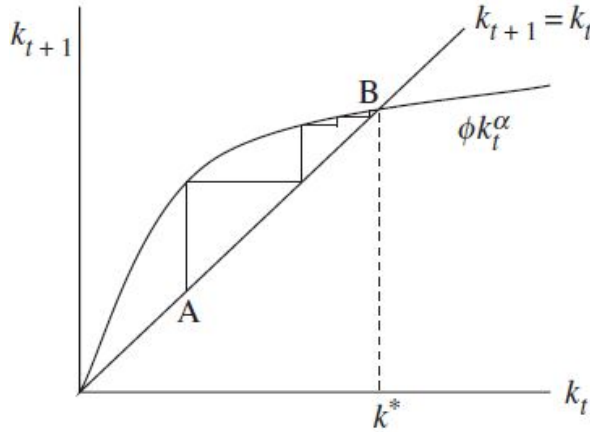

Figure 3: Wickens (2008)

In the more general CRRA case that does not assume logarithmic utility, when the return on capital exceeds the discount rate ($r_{t+1} > \theta$), a higher intertemporal elasticity of substitution ($\sigma > 1$) leads to a lower steady-state capital per worker k^* , and similarly a larger growth rate n also reduces k^* .

3.2 Pensions

There are two different types of pensions that will be analyzed in this resume: the fully funded pensions, which is characterized by "get your money, invest and give you back"; the second one is named Pay As You Go (PAYG), "get your money and pay the olders"

3.2.1 Fully Funded Pensions

In the model named as Fully Funded (FF), the pensions are provided from personal savings. There is no need to add the government in this model; however, when this occurs, the government taxes the young, invests this money, and then pays it back to the young when they become old. Assume the taxes at period t as τ_t and the investment returned for the young when they are old as p_{t+1} . This can be represented by:

$$p_{t+1} = (1 + r_{t+1})\tau_t \quad (3.28)$$

In this scheme, the budget constraint for the young generation is:

$$s_{1,t} = w_t - c_{1,t} - \tau_t \quad (3.29)$$

The consumption in the second period is:

$$\begin{aligned} c_{2,t+1} &= (1 + r_{t+1})s_t + p_{t+1}, & or \\ c_{2,t+1} &= (1 + r_{t+1})(s_t + \tau_t) \end{aligned} \quad (3.30)$$

This way, the intertemporal budget constraint is:

$$c_{2,t+1} = (1 + r_{t+1})(w_t - c_{1,t}). \quad (3.31)$$

The total economy constraint at time t is:

$$\begin{aligned} \Delta K_{t+1} &= w_t N_{1,t} + r_t K_t - c_{1,t} N_{1,t} - c_{2,t} N_{1,t-1} \\ K_{t+1} - K_t &= w_t N_{1,t} + r_t K_t - (w_t - s_t - \tau_t) N_{1,t} - (1 + r_t)(s_{t-1} + \tau_{t-1}) N_{1,t-1} \\ K_{t+1} - (s_t + \tau_t) N_{1,t} &= (1 + r_t)[K_t - (s_{t-1} + \tau_{t-1}) N_{1,t-1}] \end{aligned}$$

Taking the per capita value results in:

$$s_t + \tau_t = (1 + n)k_{t+1} \quad (3.32)$$

Note that, when $\tau_t < (1 + n)k_{t+1}$, there is no change in the total savings; the capital accumulation is the same. On the other hand, if that inequality is opposed, capital accumulation will occur.

3.2.2 Unfunded Pensions - PAYG

In this model, the old generation receives pensions through taxes paid in the current period. The government constraint is:

$$\begin{aligned} \tau(N_{1,t} + N_{2,t}) &= p_t N_{2,t} & or \\ p_t - \tau_t &= (1 + n)\tau_t \end{aligned} \quad (3.33)$$

The consumption of the old generation is:

$$\begin{aligned} c_{2,t+1} &= (1 + r_{t+1})s_t + (p_{t+1} - \tau_{t+1}) \\ &= (1 + r_{t+1})s_t + (1 + n)\tau_t \end{aligned} \quad (3.34)$$

Note that the old generation will consume the return of its private savings (r_{t+1}) and the return of the enforced pension contributions (n). The intertemporal budget constraint is:

$$c_{2,t+1} = (1 + r_{t+1})(w_t - c_{1,t} - \tau_t) + (1 + n)\tau_{t+1} \quad (3.35)$$

The capital accumulation for the PAYG is expressed by:

$$\begin{aligned} \Delta K_{t+1} &= w_t N_{1,t} + r_t K_t - c_{1,t} N_{1,t} - c_{2,t} N_{1,t-1} \\ \Delta K_{t+1} &= w_t N_{1,t} + r_t K_t - [w_t - s_t - \tau_t] N_{1,t} - [(1 + r_{t+1})(w_t - c_{1,t} - \tau_t) + (1 + n)\tau_{t+1}] N_{1,t-1} \\ K_{t+1} - (s_t + \tau_t) N_{1,t} &= (1 + r_t)[K_t - (s_{t-1} + \tau_{t-1}) N_{1,t-1}] - (n - r_t)\tau_{t-1} N_{1,t-1} \end{aligned} \quad (3.36)$$

In terms *per capita*:

$$(1 + n)k_{t+1} - (s_t + \tau_t) = \frac{1 + r_t}{1 + n}[(1 + n)k_t - (s_{t-1} + \tau_{t-1})] - \frac{n - r_t}{1 + n}\tau_{t-1}$$

The steady-state solutions when τ_t and r_t are constant is:

$$s_t = (1 + n)k_{t+1} \quad (3.37)$$

This way, the Lagrangian will be:

$$\mathcal{L} = u(c_{1,t}) - \beta u'(c_{2,t+1}) - \lambda[c_{2,t+1} - (1 + r_{t+1})(w_t - c_{1,t} - \tau_t) - (1 + n)\tau_{t+1}] \quad (3.38)$$

The F.O.C are

$$\begin{aligned} \lambda &= \frac{u'(c_{1,t})}{1 + r_{t+1}} \\ \lambda &= \beta u'(c_{2,t}) \\ \therefore u'(c_{1,t}) &= \beta(1 + r_{t+1})u'(c_{2,t}) \end{aligned}$$

Considering $u(c) = \frac{c^{1-\theta}}{1-\theta}$, that is, a CRRA, thus $u'(c) = c^{-\theta}$. Using this in the Euler equation results:

$$\begin{aligned} c_{1,t}^{-\sigma} &= \beta(1 + r_{t+1})c_{2,t}^{-\sigma} \\ c_{1,t} &= [\beta(1 + r_{t+1})]^{-\frac{1}{\sigma}} c_{2,t} \end{aligned}$$

This way, from the budget constraint and considering $\beta = 1/(1 + \theta)$:

$$\begin{aligned} c_{2,t+1} &= (1 + r_{t+1})(w_t - ([\beta(1 + r_{t+1})]^{-\frac{1}{\sigma}} c_{2,t}) - \tau_t) + (1 + n)\tau_{t+1} \\ c_{2,t+1} &= (1 + r_{t+1})(w_t - \left(\left[\frac{(1 + r_{t+1})}{1 + \theta} \right]^{-\frac{1}{\sigma}} c_{2,t} \right) - \tau_t) + (1 + n)\tau_{t+1} \end{aligned} \quad (3.39)$$

Considering $\sigma = 1$ and constant taxes results:

$$c_{2,t+1} = \frac{1 + r_{t+1}}{2 + \theta} w_t + \frac{n - r_{t+1}}{2 + \theta} \tau_t \quad (3.40)$$

Using 3.34 and 3.37 and considering $f(k_t) = k_t^\alpha$ it is possible to find that $w_t = (1 - \alpha)k_t^\alpha$ and $r_{t+1} = \alpha k_t^{-(1-\alpha)} - \delta$. This way, 3.40 could be changed into:

$$\begin{aligned} k_{t+1} &= \frac{1 - \alpha}{(2 + \theta)(1 + n)} k_t^\alpha + \frac{n - r_{t+1}}{(2 + \theta)(1 + n)(1 + r_{t+1})} \tau_t \\ &= \phi k_t^\alpha + \lambda_t \tau_t \end{aligned} \quad (3.41)$$

This way, $\lambda_t \geq 0$ then $n \geq r_{t+1}$. This can be seen in the following figure.

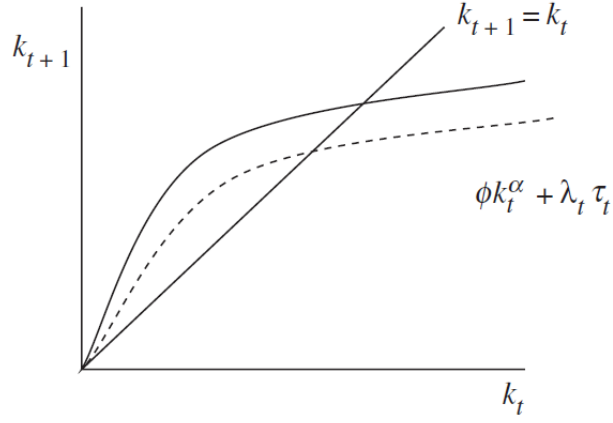

Figure 4: Wickens (2008)

The behavior of the curve depends on the relation between r_{t+1} and n . If $n > r_{t+1}$ then, $\lambda > 0$, so the changes in the unfunded pensions will shift the curve of the law of the motion of the capital upward, which means a bigger capital stock and savings, benefiting the old and young generations. On the other hand, if $n < r_{t+1}$ $\lambda < 0$. This will shift the same curve downward, which means benefits only for the old.

4 Labor and Leisure

In this section, the *Labor and Leisure* model of Chapter 7 of [4] is analyzed.

4.1 Measuring the Labor Market

Some concepts hold a central place in the discussion about the development of a single country's economy; for instance, *employed* refers to those people who have worked in the past week. *Unemployed* is a person who has not worked in the last week, but has looked for a job. Finally, *out of labor force* is a person who neither has worked nor looked for a job in the last week. This way, there is:

$$\begin{aligned}\text{Labor force} &\equiv \text{Employed} + \text{Unemployed} \\ \text{Participation Rate} &\equiv \frac{\text{Labor Force}}{\text{Population}} \\ \text{Employment Rate} &\equiv \frac{\text{Employed}}{\text{Population}} \\ \text{Unemployed Rate} &\equiv \frac{\text{Unemployed}}{\text{Labor Force}}\end{aligned}$$

4.2 A Static Model of the Labor Market

Consider the preferences of the worker as:

$$U(c, l) = u(c) + v(l), \quad (4.1)$$

where c represents consumption and l the leisure. The functions $u(c)$ and $v(l)$ are concave; therefore, they have diminishing marginal utility. Moreover, consider L as the time spent in labor.

$$\begin{aligned}L + l &= 1 \quad \text{or} \\ L &= 1 - l.\end{aligned} \quad (4.2)$$

⁵. Note that the worker must choose the best allocation of labor and leisure. Moreover, the worker has 1 unit of time to spend on labor or leisure. The wage paid to the worker is w . This way, the budget restriction is,

$$c \leq w(1 - l). \quad (4.3)$$

Consequently, the problem becomes,

$$\begin{aligned}\max_{c, l} \quad & u(c) + v(l) \\ \text{s.t.} \quad & c \leq w(1 - l)\end{aligned} \quad (4.4)$$

To solve this problem, the Lagrange multiplier could be used; that is, the Lagrange multiplier and the FOCs will be:

⁵There is another way to report this utility function of this model, that is, $U(c, L) = u(c) - z(L)$. Note that $z(L)$ is desutility of working, and that $z(L) = -v((1 - L))$ turns this equation into 4.1

$$\begin{aligned}
\mathcal{L}(c, l, \lambda) &= u(c) + v(l) - \lambda[c - w(1 - l)] \\
u'(c) - \lambda &= 0 \\
v'(l) - \lambda w &= 0 \\
v'(l) &= u'(c) * w \quad \text{or} \\
\frac{v'(l)}{u'(c)} &= w
\end{aligned} \tag{4.5}$$

4.5 shows that the marginal utility of one marginal unit of time allocated to leisure is $v'(l)$, while one more marginal unit of time spent at work will result in $w * u'(c)$ utility of this consumption. Note that this is a trade-off between leisure and consumption (labor). Moreover, consumption will increase by w units, and the worker must be indifferent to allocate their last marginal unit of time between leisure and labor. The slope of the indifference curve is given by the marginal rate of substitution of consumption and leisure, $\frac{v'(l)}{u'(c)}$, and this must be equal to the w when the budget constraint curve tangents the indifference curve. The budget constraint curve has the slope of $-w$, i.e., one more unit of leisure costs one unit more of work. This way, as the wage is w , the consumption c will decrease by $-w$ units.⁶ As shown in the following figure.

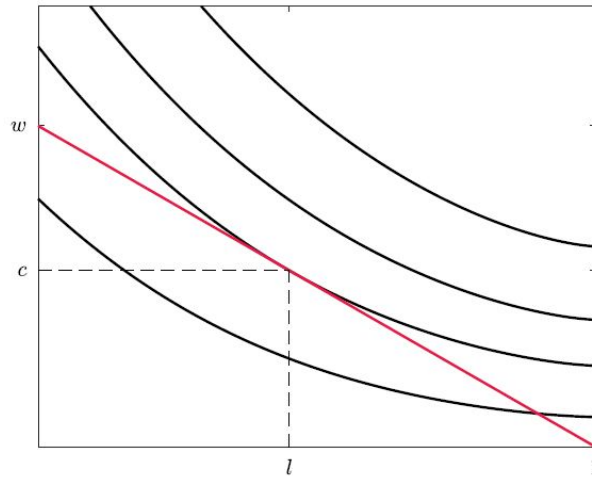

Figure 5: Source: [4]

4.2.1 The Effect of Wage Changes

The 5 shows that the maximum value of the x-axis is 1, as one would expect. This way, a change in the value of the wage represents a variation of the point w on this graph, and, consequently, a new indifference curve could be reached by the worker. Thus, a new allocation of c and l is chosen, and some of these new c and l are forced by the substitution effect and others by the income effect, as is depicted by the following figure:

⁶Note that the variation of c with regard to l is $-w$, that is the result of the derivative of 4.5 with respect to l .

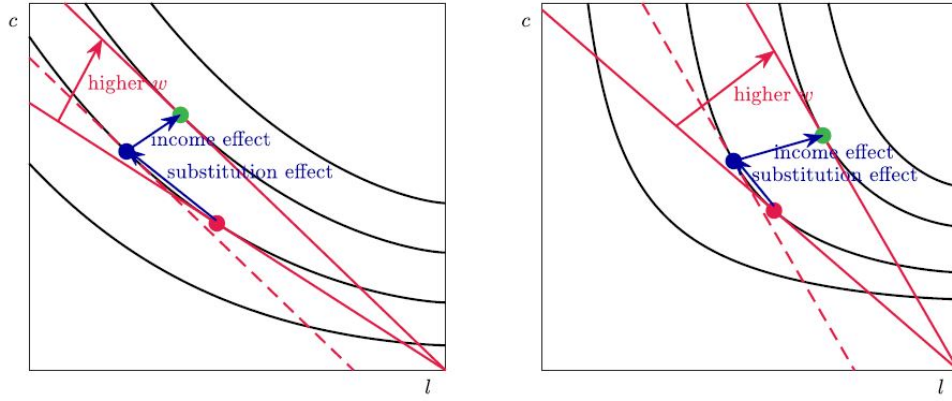

Figure 6: Source: [4]

4.2.2 Adding Taxes and Transfers

Suppose that the government collects a tax of τ on income from the worker and pays a transfer of T . The new budget constraint is:

$$c \leq w(1-l)(1-\tau) + T, \quad (4.6)$$

which demonstrates that the consumption cannot be bigger than the income plus the government transfer minus the tax deduction on the income. This new constraint could represent two types of effect. First, the transfer T indicates an upward shift in the budget constraint, which, consequently, implies that a new indifference curve will touch the budget constraint at a single point, indicating optimal worker choice. There is no change in the slope of the budget restriction; thus, the unique effect is the income effect, as the following figure indicates:

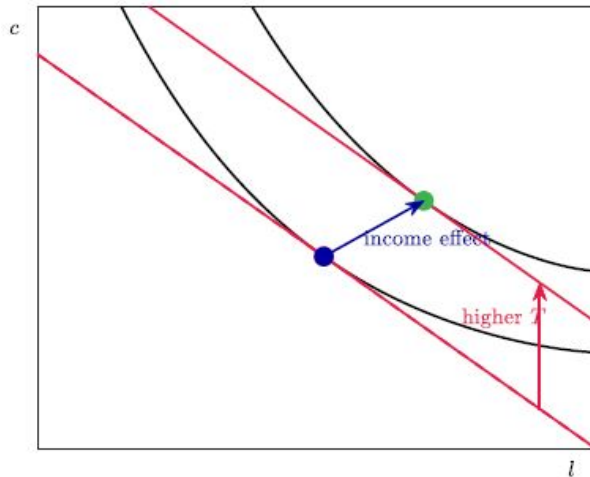

Figure 7: Source: [4]

On the other hand, the tax τ represents a change in the slope of the budget line, that is, for a given level of work, the income will be smaller, as the figure 8 shows. Note that, even if the worker chooses only leisure ($l = 1$), she will receive T , which can be used for consumption.

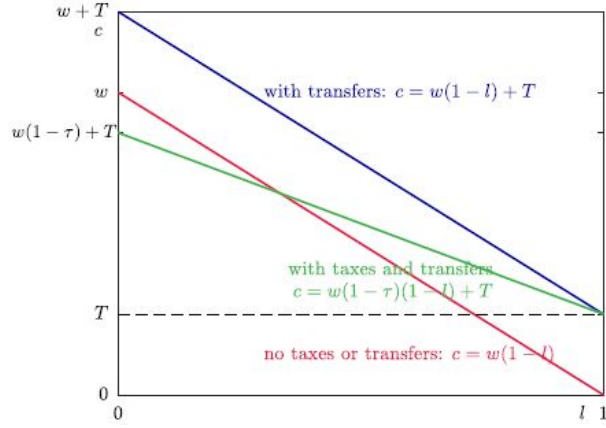

Figure 8: Source: [4]

Finally, the marginal rate of substitution of leisure for consumption is equal to the after-tax wage.

$$\frac{v'(l)}{u'(c)} = w(1 - \tau) \quad (4.7)$$

4.3 A dynamic Model

Now, suppose that there are two periods. Hence, the household must choose between the level of consumption and leisure for each period. This way, the household maximization problem is,

$$\begin{aligned} \max_{c_1, l_1, c_2, l_2} \quad & u(c_1) + v(l_1) + \beta[u(c_2) + v(l_2)] \\ \text{s.t.} \quad & c_1 + c_2 \leq w_2(1 - l_2) + \frac{1}{1+r}w_2(1 - l_2). \end{aligned} \quad (4.8)$$

⁷ Which means that the present value of the consumption must be equal to the present value of income. Moreover, β represents the discount rate, that is, how much the future consumption and leisure are valued. Therefore, the Lagrangian and FOCs for this problem are:

$$\begin{aligned} \mathcal{L}(c_1, l_1, c_2, l_2, \lambda) &= u(c_1) + v(l_1) + \beta[u(c_2) + v(l_2)] - \lambda \left[c_1 + \frac{1}{1+r}c_2 - w_2(1 - l_2) - \frac{1}{1+r}w_2(1 - l_2) \right] \\ \lambda &= u'(c_1) \\ \lambda &= \frac{v'(l_1)}{w_1} \\ \lambda &= \beta u'(c_2)(1+r) \\ \lambda &= \frac{\beta v'(l_2)(1+r)}{w_2} \end{aligned} \quad (4.9)$$

It is possible to summarize the results of 4.9 as:

⁷It is important to remember that the $1/(1+r)$ turns w_2 in present value for $t = 1$, since $w_1(1+r) = w_2$.

$$\frac{v'(l_t)}{u'(c_t)} = w_t \quad \text{for } t = 1, 2 \quad (4.10)$$

$$u'(c_1) = \beta(1 + r)u'(c_2) \quad (4.11)$$

Note that 4.10 is the same as 4.5 for each period, i.e., the household is indifferent between allocating one marginal utility of time in leisure or in the work market, since the income is w . 4.11, on the other hand, indicates the *Euler equation* for this dynamic model of labor and leisure with two periods, that is, the distribution of consumption over time.

Assuming that v' has an inverse function $(v')^{-1}$, since $v(l_1)$ is concave, it is possible to get the following result that helps to understand the behavior of the household if the wage rises.

$$\begin{aligned} \frac{v'(l_1)}{u'(c_1)} &= w_1 \\ v'(l_1) &= w_1 u'(c_1) \\ l_1 &= (v')^{-1}[w_1 u'(c_1)] \\ L &= 1 - [(v')^{-1}[w_1 u'(c_1)]] \end{aligned} \quad (4.12)$$

8

Comparing two scenarios, one in which only w_1 rises, while the other one, both w_1 and w_2 rise. In the first case, c_1 increases slightly because the intertemporal consumption mechanism, which smooths consumption between two periods, is in effect. In the second scenario, there will be a larger increase in c_1 , since the wage is higher in both periods. Since $u'(c_1)$ is decreasing, a larger c_1 results in a smaller $u'(c_1)$. This way, as $(v')^{-1}$ is decreasing, and also as the inverse function will be applied on $w_1 u'(c_1)$, if $u'(c_1)$ is smaller, then $(v')^{-1}[w_1 u'(c_1)]$ is bigger, once that w_1 is the same for temporary and permanent rise in wage. This way, it is possible to conclude that L at $L = 1 - [(v')^{-1}[w_1 u'(c_1)]]$ will be smaller, meaning that the household chooses to allocate less time in the work market.

⁸Remember 4.2 for the last line.

5 Investment

In this section, the *Investment* decision of Chapter 8 of [4] is analyzed.

First of all, the interest rate is essential for investment decisions. Consider a two-period model where a representative agent is considering building a factory, which has a total cost of 1000 units of consumption of the unique good of the economy. This factory will be built in period one and will generate a revenue of 2,500 in the second period. The cost of operation in the last period is 1,400 units. Of course, the revenue is greater than the costs in the second period, and the net revenue from this is 1,100, which is also greater than the cost to build the factory in the first period. Even so, the conclusion about building this firm is not clear, since the value of 1,000 of the unique good is not necessarily 1,000; the present value of this amount is $1,000 * (1+r)$, where r is the interest rate. Thus, $1,000 * (1+r) > 1,100$, to build the factory is worth it, or in other terms, if $r > 0.1$ the right choice is to invest.⁹

5.1 Present Value

Consider an investment that pays d_t as a dividend in period t . To obtain the value of this dividend of time t in present value in period 0, is given by the following equation:

$$V = \sum_{t=1}^{\infty} \frac{d_t}{(1+r)^t} \quad (5.1)$$

This way, an investment project is worthwhile if the net present value is positive, that is, if $NPV \equiv V - I > 0$. For the example used before,

$$\begin{aligned} NPV &= V - I \\ &= \frac{1100}{1+r} - 1000 \end{aligned}$$

That is, the investment is worthwhile only if $r < 0.1$.

Suppose that the dividends grow at a rate g forever, thus $d_{t+1} = (1+g)d_t$ or $d_t = d_1(1+g)^{t-1}$. Thus, V is:

$$\begin{aligned} V &= \sum_{t=1}^{\infty} \frac{d_1(1+g)^{t-1}}{(1+r)^t} \\ V &= \frac{d_1}{1+g} \sum_{t=1}^{\infty} \left(\frac{1+g}{1+r} \right)^t \quad (\text{Applying formula for a geometric sum}) \\ V &= \frac{d_1}{r-g} \quad (\text{simplifying}) \end{aligned} \quad (5.2)$$

This is the Gordon growth formula that shows that a higher interest rate means a lower dividend paid in the future in present value. Sometimes it is not easy to measure the present value of, for example, rental income and compare it with the cost of the construction of a building. Backing to 5.1, there are no guarantees that the interest rate or the dividend will keep the value r and d_t in the future, since there are a lot of

⁹Note that as the value of 1,000 units of the good in the first period is given by $1,000 * (1+r)$, the value of the same amount from the second period to the first one is given by $1,000/(1+r)$

macroeconomic factors that will influence that. This way, analyzing asset prices in the stock market could be a good choice to determine if making an investment in this type of asset is a good decision, as the Tobin's Q model tries to explain:

$$Q \equiv \frac{\text{Market Value}}{\text{Book Value}} \quad (5.3)$$

where *Market Value* refers to the price of the same asset in the market, while the *Book Value* refers to the amount of the investment that will be necessary to construct a replica of this asset; therefore, if $Q > 1$, it means that investing is a good idea, on the other hand, if $Q < 1$, there must be no investment.

There is a more flexible concept about the decision of making an investment or not, that is, the adjustment of cost. Suppose that a firm has K capital and wants to expand its operations with the investment I . Then, the new level of capital is $K' = K + I$, i.e., the adjustment of cost is the function $\Psi(I, K)$ that informs how much a firm needs to make this expansion to K' , since K is its level of capital and I is the total of investment. One of the forms of this function is:

$$\Psi(K, I) = \frac{\psi I^2}{2K} \quad (5.4)$$

The derivative of this function with respect to I is $\psi \frac{I}{K}$, i.e., these adjustment costs are higher when the investment I is far higher than the firm's capital.

The firm's problem for this model will be to decide how much to invest (I) today, given the capital K and its stock market value QK . Therefore:

$$\max_I Q(K + I) - \left(I + \frac{\psi I^2}{2K} \right) \quad (5.5)$$

That is, the firm wants to maximize its market value minus the cost of expansion and adjustment cost (net profit from investing), choosing I . Therefore, the first order conditions are:

$$\begin{aligned} Q - 1 - \frac{\psi I}{K} &= 0 \\ \frac{I}{K} &= \frac{1}{\psi}(Q - 1) \end{aligned}$$

That is, the investment rate relative to the size of the firm (I/K) is proportional to the extent to which Tobin's Q exceeds 1.

5.2 Risk

It is important to point out that, frequently, the dividends are not known; that is, the value of d_t depends on the state of the world at t . Suppose a two-period situation, where the d_s depends on the rain, paying $d_s = 100$ if it rains and $d_s = 8$ if it does not. The interest rate is 10%. So, a household must decide whether to invest or not p in period 1 in this firm. The household consumes c_1 in the first period and $c_2(s)$ in the second. The state s is what happens in the second period, and the probability of the state is $Pr(s)$. Furthermore, the probability of it raining is 0.75. It is necessary to find a value of p that makes the household indifferent between investing in the project or not. Therefore, the household's problem becomes:

$$\max_x u(c_1 - xp) + \beta \sum_s Pr(s)u(c_2(s) + xd(s)) \quad (5.6)$$

Therefore, the family must choose x unities of the project, which means diminishing the consumption in the first period by xp and increasing it in the second period by $Pr(s) * xd(s)$. Thus, the first order condition becomes,

$$-pu'(c_1 - xp) + \beta \sum_s Pr(s)u'(c_2(s) + xd(s))d(s) = 0$$

Note that the problem is seeking a value of p which turns the household indifferent between buying or not one more unit of the asset; therefore, a price which has int in the optimization situation, $x = 0$. Substituting and rearranging for p , the results is,

$$p = \frac{\beta \sum_s Pr(s)u'(c_2(s))d(s)}{u'(c_1)}$$

Consider that it holds the intertemporal maximization of the consumption of c_1 and c_2 , therefore, the *Euler Equation* is,

$$u'(c_1) = \beta(1 + r) \sum_s Pr(s)u'(c_2(s)) \quad (5.7)$$

Replacing c_1 ,

$$p = \frac{1}{1 + r} \frac{\sum_s Pr(s)u'(c_2(s))d(s)}{\sum_s Pr(s)u'(c_2(s))} \quad (5.8)$$

This indicates that, with risk, the present value of an asset is given by a discounted ($1/(1 + r)$) weighted average of the dividends; this weight is proportional to the marginal utility of $c_2(s)$. Therefore, as the marginal utility is a decreasing function, when $c_2(s)$ is low, the marginal utility $u'(c_2(s))$ will be high, so dividends in those states receive greater weight, making assets that pay off in bad times more valuable. Considering, $u'(c_2(s))$ for all s , then,

$$\begin{aligned} p &= \frac{1}{1 + r} \frac{u'(c_2(s)) \sum_s Pr(s)d(s)}{u'(c_2(s)) \sum_s Pr(s)} \\ &= \frac{\sum_s Pr(s)d(s)}{1 + r} \\ &= \frac{\mathbb{E}(d)}{1 + r} \end{aligned} \quad (5.9)$$

Suppose that $c_2(d) = c$ and assuming that $Cov(X, Y) = \mathbb{E}(XY) - \mathbb{E}(X)\mathbb{E}(Y)$. Therefore, 5.8 could be expressed by

$$p = \frac{\mathbb{E}(d) + Cov(d, u'(c))}{1 + r} \quad (5.10)$$

This indicates that the value of the asset that pays more in bad times is bigger than those that pay more in good times, and moreover, when the covariance in 5.10 is positive, it means that the dividend pays more and the variation of the marginal utility of consumption has the same direction as the dividends.¹⁰

¹⁰It is possible to think about the dividends delivery more income in hard times, thus the household chooses to pays more in for this investment.

6 General Equilibrium

In this section, we analyze the general equilibrium model from Chapter 9 of [4]. The model's main contribution is a clearer characterization of equilibrium between firms and households, i.e., the simultaneous clearing of supply and demand across markets. In macroeconomic terms, a real equilibrium arises when every buyer obtains the quantity they desire and every seller supplies the quantity they wish. The economy is represented by three agents: a representative household that chooses consumption, savings and leisure; a representative firm that chooses between renting capital and hiring labor; and an investment firm that determines the allocation of new investment projects

6.1 General Equilibrium in a Two-Period Economy

Consider a two-period model. In period one, the K_1 is the capital of this economy, which is owned by a representative household. The production function is $F(K, L)$ and δ_1 is the depreciation rate in the first period. In the second period, all the capital is consumed, so $\delta_2 = 1$ and is the end of the world.

This way, the household problem is

$$\begin{aligned} \max_{c_1, l_1, c_2, l_2} \quad & u(c_1) + v(l_1) + \beta[u(c_2) + v(l_2)] \\ \text{st} \quad & c_1 + \frac{1}{1+r}c_2 \leq w_1(1-l_1) + \frac{1}{1+r}w_2(1-l_2) + K_1(1+r_1^K - \delta) + \Pi \end{aligned} \quad (6.1)$$

Note that there are differences between this equation and that one for the labor-leisure model for the dynamic model 4.8, that is, now there is an initial capital stock (K_1), which has net rental $(1+r_1^K - \delta)$. The other difference is a consequence of the family being the owner of the firm, so that it can get a profit in the firm's operation Π . Therefore, the profit of the firm is in the budget constraint. Π is described by $\Pi = \Pi_1^F + \frac{\Pi_2^F}{1+r} + \Pi^I$; Π_t^F represents the firm's productive profit in period t and Π^I and is the firm's profit of investments.¹¹ This way, the representative firm seeks the profit maximization, that is, its problem is:

$$\Pi_t^F = \max_{K, L} F(K, L) - w_t L - r_t^K K \quad (6.2)$$

There is another firm that makes the investments; therefore, it buys $(1-\delta)K_1$, adds I units of investment and obtains $K_2 = I + (1-\delta)K_1$. This firm rents K_2 units of capital at a rate r_2^K . The discount for this is $\frac{r_2^K}{1+r}K_2$. Therefore, the investment firm's problem is:

$$\Pi^I = \max_l \frac{r_2^K}{1+r}[I + (1-\delta)K_1] - [(1-\delta)K_1 + I] \quad (6.3)$$

The first term of 6.3 represents the present value of rental K_2 while the second one is the cost of K_2 .

¹¹It is crucial to point out that in the equilibrium $\Pi = 0$

6.1.1 Equilibrium Definition

For an initial capital of K_1 , there will be an allocation of $c_1, l_1, c_2, l_2, I, K_2, L_1, L_2$ at prices $w_1, w_2, r_1^K, r_2^K, r$ that solves the household's problem with c_1, l_1, c_2, l_2 , the production firm's problem with L_1, L_2, K_1, K_2 , given the prices. And the problem of the investment firm with I . Moreover, in each period, the market for goods and labor:

- Goods:

$$\begin{aligned} F(K_1, L_1) &= c_1 + I \\ F(K_2, L_2) &= c_2^{12} \end{aligned} \tag{6.4}$$

- Capital:

$$K_2 = K_1(1 - \delta) + I^{13} \tag{6.5}$$

- Labor:

$$L_t + l_t = 1^{14} \tag{6.6}$$

6.1.2 Describing an Equilibrium

This subsection demonstrates the equations based on the previous sections that represent the competitive equilibrium. From the leisure-labor model, it is known that:

$$\frac{v'(l_t)}{u'(c_t)} = w_t \tag{6.7}$$

$$u'(c_1) = \beta(1 + r)u'(c_2) \tag{6.8}$$

6.7 indicates how the household trades consumption for leisure, while 6.8 informs how the household trades consumption in period one for consumption in period 2. The firm's production has the following equations to solve its maximization problem,

$$F_K(K_t, L_t) - r_t^K = 0 \tag{6.9}$$

$$F_L(K_t, L_t) - w_t = 0 \tag{6.10}$$

6.9 and 6.10 inform that the marginal product of capital and labor is equal to their marginal cost.

In the capital-market clearing, the investment firm has the solution given by:

$$1 + r = r_2^K \tag{6.11}$$

Plugging 6.10 into 6.7 results in:

¹²There is no Investment in the second period, only consumption.

¹³The capital in the second period will be equal to the initial capital less the depreciation plus the investment that occurred in the first period.

¹⁴That is, all the labor hire plus the time the household dedicates to the leisure is equal to the normalized time available, that is, 1.

$$\frac{v'(l_t)}{u'(c_t)} = F_L(K_t, L_t) \quad (6.12)$$

This indicates that the marginal rate of substitution of leisure for consumption is equal to the marginal rate of transformation of time in production.

Plugging 6.11 and 6.9 into 6.8 results in:

$$\frac{u'(c_1)}{\beta u'(c_2)} = F_K(K_2, L_2) \quad (6.13)$$

This indicates that the marginal rate of substitution of present consumption for future consumption, that is, how the family is willing to trade present consumption for future consumption, is equal to the marginal rate of transformation of time in production. 6.12 and 6.13 demonstrates how the general equilibrium looks like.

6.2 The First Welfare Theorem

The First Welfare Theorem demonstrates that the allocation of a competitive market is the best one. Suppose the existence of a benevolent social planner that has to choose the best allocation of $c_1, l_1, c_2, l_2, L_1, L_2, K_2$, he/she has to solve the following problem:

$$\begin{aligned} \max_{c_1, l_1, c_2, l_2, L_1, L_2, K_2} \quad & u(c_1) + v(l_1) + \beta[u(c_2) + v(l_2)] \\ \text{st} \quad & \\ & K_2 \leq (1 - \delta)K_1 + F(K_1, L_1) - c_1 \\ & c_2 \leq F(K_2, L_2) \\ & L_t \leq 1 - l_t \quad \text{for } t = 1, 2 \\ & K_1 \text{ given} \end{aligned} \quad (6.14)$$

Let's take equality for $c_1 = (1 - \delta)K_1 + F(K_1, L_1) - K_2$, $c_2 = F(K_2, L_2)$ and $l_t = 1 - L_t$, this way, 6.14 becomes:

$$\max_{L_1, L_2, K_2} \quad u((1 - \delta)K_1 + F(K_1, L_1) - K_2) + v(1 - L_1) + \beta[u(F(K_2, L_2)) + v(1 - L_2)] \quad (6.15)$$

So, FOC's for L_1, L_2, K_2 are:

$$\begin{aligned} u'((1 - \delta)K_1 + F(K_1, L_1) - K_2)F_L(K_1, L_1) - v'(1 - L_1) &= 0 \\ \beta[u'(F(K_2, L_2))F_L(K_2, L_2) - v'(1 - L_2)] &= 0 \\ -u'((1 - \delta)K_1 + F(K_1, L_1) - K_2) + \beta u'(F(K_2, L_2))F_{K_2}(K_2, L_2) &= 0 \end{aligned}$$

It is possible to simplify these FOC to those for the model of the competitive equilibrium. Thus, it is possible to conclude that the social planner's allocation is equal to that of the competitive market, which is the optimal allocation. The reason for the equality between the social planner's allocation and the competitive market is that the former depends on the technology available. At the same time, the latter is based on the price, which reflects the technology again; thus, the result will be the same for both. This way, the FWT holds when there are many goods to be consumed, technological progress, uncertainty,

and different household preferences¹⁵. Finally, it does not hold when an economy has a monopoly or externalities¹⁶.

6.3 General Equilibrium in an Infinite-Period Economy

For an infinite-period economy, there will be minor changes in the problem, but the steps to find the optimal allocation will be the same: describe the household's problem, the firm's problem, the investment decision, and the equilibrium. This way, the household's problem is:

$$\begin{aligned} \max_{c_t, l_t, a_{t+1}} \quad & \sum_{t=0}^{\infty} \beta^t [u(c_t) + v(l_t)] \\ \text{s.t.} \quad & a_{t+1} = (1 + r_t)a_t + w_t(1 - l_t) + \prod_t^F + \prod_t^I - c_t \\ & a_0 = K_0(1 - r_0^K - \delta) \quad \text{given} \\ & \lim_{T \rightarrow \infty} \frac{a_T}{(1 + r)^T} \geq 0 \quad \text{A no-Ponzi-game condition} \end{aligned} \tag{6.16}$$

Note that $a_{t+1} = (1 + r_t)a_t + w_t(1 - l_t) + \prod_t^F + \prod_t^I - c_t$ is the budget constraint to the household problem. Moreover, the no-Ponzi game indicates that there are no infinite debts. Still, there is a connection between the two following periods with this budget constraint. The productive firm's problem is the same for the two-period model. On the other hand, the investment firm has the following problem:

$$\prod_t^I = \max_I \frac{r_{t+1}^K + 1 - \delta}{1 + r_{t+1}} [K_t(1 - \delta) + I] - [K_t(1 - \delta) + I] \tag{6.17}$$

The solution for those problems will be the sequence of arrays $\{c_t, l_t, I_t, K_{t+1}, L_t\}_{t=0}^{\infty}$ based on the prices $\{w_t, r_t^K, r_t\}_{t=0}^{\infty}$. Note that $\{c_t, l_t\}_{t=0}^{\infty}$, L_t, K_t, I_t solve the problems of the household, productive firm, and investment firm, respectively. Moreover, at the market equilibrium,

- Goods Market: $F(K_t, L_t) = c_t + I_t$;
- Capital Market: $K_{t+1} = K_t(1 - \delta) + I_t$
- Labor Market: $L_t + l_t = 1$

Consequently, the first-order condition to the household's problem is given by:

$$\frac{v'(l_t)}{u'(c_t)} = w_t \tag{6.18}$$

$$u'(c_t) = \beta(1 + r_{t+1})u'(c_{t+1}) \tag{6.19}$$

The firm's problem FOC is:

$$F_K(K_t, L_t) - r_t^K = 0 \tag{6.20}$$

$$F_L(K_t, L_t) - w_t = 0 \tag{6.21}$$

¹⁵For different household preferences, some adaptation must be imposed for the FWT

¹⁶For more details, see [4]

The investment firm is:

$$r_{t+1} = r_{t+1}^K - \delta \quad (6.22)$$

Again, it is possible to plug these equations into one another to obtain some insightful results,

$$\frac{v'(l_t)}{u'(c_t)} = F_L(K_t, L_t) \quad (6.23)$$

Again, the marginal rate of substitution between leisure and consumption is equal to the marginal rate of transformation of time into production. The following equation shows that the marginal rate of substitution of consumption between the two following periods will be equal to the marginal rate of transformation of capital in production, that is,

$$\frac{u'(c_t)}{\beta u'(c_{t+1})} = (1 + F_K(K_{t+1}, L_{t+1}) - \delta) \quad (6.24)$$

6.3.1 Dynamics

Considering the long-term behavior of the economy is a common approach in economic analysis. Suppose $L_t = 1$ and $u(c) = \frac{c^{1-\sigma}}{1-\sigma}$. This way, 6.24 becomes,

$$\frac{c_{t+1}}{c_t} = [\beta(1 + F_K(K_{t+1}, 1) - \delta)]^{\frac{1}{\sigma}} \quad (6.25)$$

This demonstrates the relation between the rate of growth of consumption between t and $t + 1$ and the level of capital stock at $t + 1$. Suppose that the capital stock at $t + 1$ is low; thus, as a consequence of diminishing marginal product, the marginal product of capital is high. So, from 6.9 it is possible to conclude that the capital rental is also high. This way, as a consequence of 6.11, the interest rate will be high. Therefore, future consumption is more attractive than present consumption, as demonstrated by the Euler Equation, which means a growth in consumption as was supposed before.

From the assumptions about L_t and $u(c)$, the market clearing for capital between two periods is:

$$K_{t+1} = (1 - \delta)K_t + F(K_t, 1) - c_t \quad (6.26)$$

Note that (6.26) shows the relation between future capital stock, current capital stock and current consumption, when the family has a higher level of consumption at time t this means less capital stock at time $t + 1$.

The following graphic shows the dynamics of this Neoclassical Growth Model:

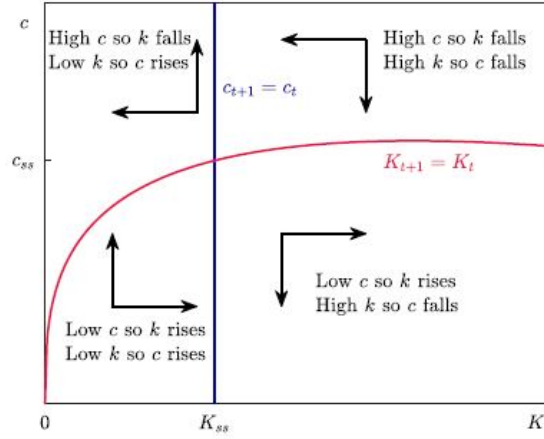

Figure 9: Source: [4]

Note that the constant consumption requires that $\frac{c_{t+1}}{c_t} = 1$. Consequently, since (6.25), $[\beta(1 + F_K(K_{t+1}, 1) - \delta)]^{\frac{1}{\sigma}} = 1$. Therefore, $F_K(K_{t+1}, 1) - \delta = \frac{1}{\beta} - 1$, that is, $\frac{1}{\beta} - 1$ must be the interest rate to keep a constant consumption. For the capital, it is known that $K_{t+1} = K_t$, i.e., $(1 - \delta)K_t + F(K_t, 1) - c_t = K_t$ and $c_t = F(K_t, 1) - \delta K_t$, which must be the consumption level to keep the capital stock constant; if the consumption rises so that the investment will fall and the capital stock will diminish.

The path to the steady-state depends on the level of consumption at $t = 0$. K_0 is given, so there is a necessity to know c_0 ; the level of the initial consumption c_0 , given K_0 , must be in accordance with the Euler equation, otherwise the consumption or the capital will collapse. The following graph demonstrates that:

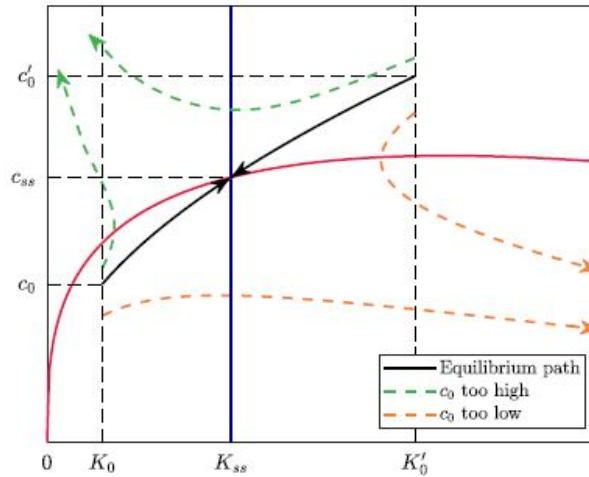

Figure 10: Source: [4]

Consider two different points c_0 for the first period consumption. The black arrows show the saddle paths, that is, the paths that bring the economy to the steady-state; they are narrow. Note that, for an initial consumption higher than c_0 , the green arrows indicate that all in the economy will be consumed, since the consumption is bigger than the necessary to make up the depreciation of the capital. On the other hand, if the initial consumption is lower than c_0 , then all in the economy, in the long run, will be invested and nothing will be consumed, as is shown by the orange arrows. The same behavior is

seen for c'_0 . Thus, the saddle path will bring the economy to the saddle point, which is the steady-state, where the consumption is constant, as well as capital.

6.3.2 The Golden Rule

The Golden Rule comes from Solow's model and states the level of the capital K_{gr} that has the steady state maximized. However, the question is, how is the consumption and savings model's capital, K_{ss} , related to K_{gr} ? From the Solow's model:

$$F_K(K_{gr}, 1) = \delta \quad (6.27)$$

The endogenous savings model satisfies that $F_K(K_{t+1}, 1) - \delta = \frac{1}{\beta} - 1$, therefore:

$$\begin{aligned} F_K(K_{ss}, 1) - \delta &= \frac{1}{\beta} - 1 \\ &> \delta \quad \text{as long as } \beta < 1 \\ &= F_K(K_{gr}, 1) \\ &\Rightarrow K_{ss} < K_{gr} \end{aligned} \quad (6.28)$$

The last inequality of (6.28) comes from diminishing marginal product; thus, if the marginal product of K_{ss} is bigger than the marginal product of K_{gr} , then $K_{ss} < K_{gr}$. This result is a consequence of the household's impatience; the household prefers to consume a little more in the present, even at the expense of a lower level of consumption in the future, which could be achieved with the Golden Rule's level of capital. Note that a patient household has $\beta = 1$, so, from (6.28), $K_{ss} = K_{gr}$ and the consumption will be maximized.

6.3.3 Anticipation Effects

Thinking in terms of general equilibrium helps us understand how expectations about future events affect present decisions.

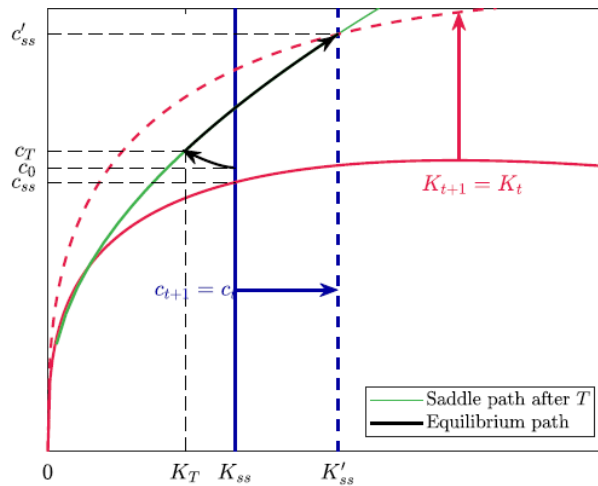

Figure 11: Source: [4]

As shown in the previous figure, if agents anticipate a future technological improvement that increases productivity, this shifts the economy's future steady state. Even before the innovation occurs, consumption rises immediately due to a wealth effect, while investment

falls, causing the capital stock to shrink. As capital declines, the marginal product of capital and interest rates rise, which supports a path of gradually increasing consumption. By the time the new technology is implemented, the economy's capital and consumption levels have adjusted so that it lies exactly on the new saddle path leading to the higher steady state.

7 Calculus of Variations

The **calculus of variations** is a branch of mathematics concerned with extremizing (maximizing or minimizing) *functionals* — that is, mappings that take functions as arguments and return real numbers. In dynamic economics, this tool is fundamental for intertemporal optimization problems, such as growth models and consumption-savings decisions over time. The standard references for this section are Sydsæter *et al.* (ch. 8) [6] and Chiang (chs. 2–6) [2].

7.1 Statement of the problem

The fundamental problem of the calculus of variations consists in finding a function $y(x)$ that extremizes the functional

$$V(y) = \int_{x_1}^{x_2} F(x, y(x), y'(x)) dx,$$

subject to the boundary conditions

$$y(x_1) = A, \quad y(x_2) = B,$$

where A and B are given constants. Geometrically, we seek, among all curves joining (x_1, A) to (x_2, B) , the one that renders the integral as small (or as large) as possible.

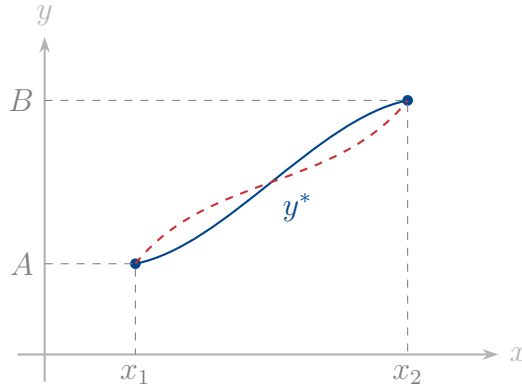

Figure 12: Among all admissible curves connecting the boundary points, we seek the curve $y^*(x)$ that extremizes the functional.

7.2 Derivation of the Euler-Lagrange equation

Suppose $y^*(x)$ is a solution of the problem and consider small variations around this curve. Write

$$y(x) = y^*(x) + \delta y(x), \quad y'(x) = (y^*)'(x) + (\delta y)'(x),$$

where the perturbation δy vanishes at the endpoints, i.e. $\delta y(x_1) = \delta y(x_2) = 0$, since the boundary points are fixed.

The first-order variation of the functional is

$$\delta S = \int_{x_1}^{x_2} \left[\frac{\partial F}{\partial x} \delta x + \frac{\partial F}{\partial y} \delta y + \frac{\partial F}{\partial y'} \delta y' \right] dx.$$

Assuming $\delta x = 0$ (the independent variable is not varied), we are left with

$$\delta S = \int_{x_1}^{x_2} \frac{\partial F}{\partial y} \delta y \, dx + \int_{x_1}^{x_2} \frac{\partial F}{\partial y'} (\delta y)' \, dx.$$

Applying **integration by parts** to the second term, with $u = \partial F / \partial y'$ and $dv = (\delta y)' \, dx$, we obtain

$$\int_{x_1}^{x_2} \frac{\partial F}{\partial y'} (\delta y)' \, dx = \left. \frac{\partial F}{\partial y'} \cdot \delta y \right|_{x_1}^{x_2} - \int_{x_1}^{x_2} \frac{d}{dx} \left(\frac{\partial F}{\partial y'} \right) \delta y \, dx.$$

Since δy vanishes at the endpoints, the boundary term drops out, and

$$\delta S = \int_{x_1}^{x_2} \left[\frac{\partial F}{\partial y} - \frac{d}{dx} \left(\frac{\partial F}{\partial y'} \right) \right] \delta y \, dx.$$

For y^* to be an extremal, we must have $\delta S = 0$ for *every* admissible perturbation δy . By the *fundamental lemma of the calculus of variations*, this forces the integrand in brackets to vanish identically:

Euler-Lagrange equation

$$\frac{\partial F}{\partial y} - \frac{d}{dx} \left(\frac{\partial F}{\partial y'} \right) = 0.$$

Remark. Expanding the total derivative with respect to x via the chain rule,

$$\frac{d}{dx} \left(\frac{\partial F}{\partial y'} \right) = \frac{\partial^2 F}{\partial x \partial y'} + \frac{\partial^2 F}{\partial y \partial y'} \cdot y' + \frac{\partial^2 F}{\partial (y')^2} \cdot y'',$$

the Euler-Lagrange equation may be rewritten as

$$F_{y'x} + F_{y'y} y' + F_{y'y'} y'' - F_y = 0,$$

a second-order ordinary differential equation in $y(x)$.

7.3 Classical examples

Example 7.1. (*Shortest distance between two points in the plane*) Let $A = (x_A, y_A)$ and $B = (x_B, y_B)$ be two points in the plane. Among all curves connecting them, which has the shortest length?

By the Pythagorean theorem, an infinitesimal arc element satisfies

$$ds^2 = dx^2 + dy^2 = dx^2 \left[1 + \left(\frac{dy}{dx} \right)^2 \right],$$

so that

$$ds = \sqrt{1 + (y')^2} \, dx.$$

The total length is therefore

$$S_{AB} = \int_{x_A}^{x_B} \sqrt{1 + (y')^2} \, dx,$$

with $F(x, y, y') = \sqrt{1 + (y')^2}$. Since F does not depend explicitly on y , we have $\partial F / \partial y = 0$, and the Euler-Lagrange equation reduces to

$$\frac{d}{dx} \left(\frac{y'}{\sqrt{1 + (y')^2}} \right) = 0.$$

This implies that $y' / \sqrt{1 + (y')^2}$ is constant, whence $y' = a$ is constant. Integrating,

$$y(x) = ax + b.$$

Imposing the boundary conditions $y(x_A) = y_A$ and $y(x_B) = y_B$, we obtain

$$a = \frac{y_B - y_A}{x_B - x_A}, \quad b = y_B - \left(\frac{y_B - y_A}{x_B - x_A} \right) x_B.$$

Conclusion: the shortest curve is the straight line, as expected.

Example 7.2. (the brachistochrone problem) Posed by Johann Bernoulli in 1696, the **brachistochrone problem** asks: given two points A and B in a vertical plane, with B below and to the side of A , along which curve should a bead slide, under gravity alone, starting from rest, without friction, so as to reach B in the shortest possible time?

Place A at the origin, with the x -axis horizontal and the y -axis pointing downward. Let $y(x)$ describe the curve, with $y(0) = 0$ and $y(x_B) = y_B > 0$.

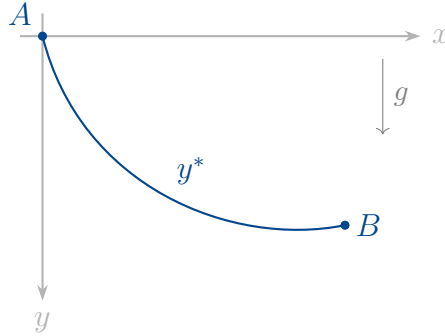

Figure 13: The brachistochrone: the curve of fastest descent between A and B under gravity.

By conservation of energy, a bead that has fallen a vertical distance y from rest has speed $v = \sqrt{2gy}$. The infinitesimal time to traverse an arc element $ds = \sqrt{1 + (y')^2} dx$ is

$$dt = \frac{ds}{v} = \frac{\sqrt{1 + (y')^2}}{\sqrt{2gy}} dx,$$

so that the total descent time is the functional

$$T(y) = \frac{1}{\sqrt{2g}} \int_0^{x_B} \sqrt{\frac{1 + (y')^2}{y}} dx, \quad F(y, y') = \sqrt{\frac{1 + (y')^2}{y}}.$$

Applying the Euler-Lagrange equation, $\frac{\partial F}{\partial y} - \frac{d}{dx} \left(\frac{\partial F}{\partial y'} \right) = 0$, we compute

$$\frac{\partial F}{\partial y} = -\frac{1}{2} \cdot \frac{\sqrt{1 + (y')^2}}{y^{3/2}}, \quad \frac{\partial F}{\partial y'} = \frac{y'}{\sqrt{y} \sqrt{1 + (y')^2}}.$$

The Euler-Lagrange equation therefore reads

$$\frac{d}{dx} \left[\frac{y'}{\sqrt{y(1+(y')^2)}} \right] + \frac{1}{2} \cdot \frac{\sqrt{1+(y')^2}}{y^{3/2}} = 0.$$

Expanding the total derivative via the chain rule and multiplying through by $2\sqrt{y(1+(y')^2)}$ leads, after algebraic simplification, to the second-order ODE

$$2y y'' + (y')^2 + 1 = 0.$$

To solve it, use the standard trick $y'' = y' \frac{dy'}{dy}$, which reduces the equation to a first-order ODE in y' as a function of y :

$$2y y' \frac{dy'}{dy} + (y')^2 + 1 = 0.$$

Letting $u := (y')^2$, we have $\frac{du}{dy} = 2y' \frac{dy'}{dy}$, so the equation becomes linear in u :

$$y \frac{du}{dy} + u = -1 \quad \Longleftrightarrow \quad \frac{d}{dy}(y u) = -1.$$

Integrating, $y u = -y + C_1$, hence

$$(y')^2 = \frac{C_1 - y}{y} \quad \Longleftrightarrow \quad y(1 + (y')^2) = C_1 =: k.$$

This is a first-order ODE for $y(x)$. Separating variables,

$$dx = \sqrt{\frac{y}{k-y}} dy.$$

The substitution $y = \frac{k}{2}(1 - \cos \theta)$ transforms the integrand, and integrating with $x = 0$ at $\theta = 0$, we obtain the parametric solution

$$\boxed{x(\theta) = \frac{k}{2}(\theta - \sin \theta), \quad y(\theta) = \frac{k}{2}(1 - \cos \theta)}$$

which describes a **cycloid**, the curve traced by a point on the rim of a wheel of radius $k/2$ rolling along the x -axis. The constant k is determined by the condition that the curve pass through B .

Example 7.3. (The cake-eating problem) A consumer has an initial stock of cake $W_0 > 0$ that will be entirely consumed over a fixed horizon $[0, T]$. Let $c(t) \geq 0$ denote the consumption rate and $W(t)$ the remaining stock. The cake evolves according to

$$\dot{W}(t) = -c(t), \quad W(0) = W_0, \quad W(T) = 0.$$

The consumer derives instantaneous utility $U(c)$ with $U'(c) > 0$ and $U''(c) < 0$, and discounts future utility at rate $\rho > 0$. The problem is

$$\max_{c(\cdot)} \int_0^T U(c(t)) e^{-\rho t} dt.$$

Since $c = -\dot{W}$, we may rewrite the functional in terms of W alone:

$$\max_{W(\cdot)} \int_0^T \underbrace{U(-\dot{W}) e^{-\rho t}}_{= F(t, W, \dot{W})} dt, \quad W(0) = W_0, \quad W(T) = 0.$$

Note that F does not depend explicitly on W , so $\partial F / \partial W = 0$. The Euler-Lagrange equation becomes

$$-\frac{d}{dt} \left(\frac{\partial F}{\partial \dot{W}} \right) = 0 \quad \Longleftrightarrow \quad \frac{\partial F}{\partial \dot{W}} = \text{constant}.$$

Computing the partial derivative:

$$\frac{\partial F}{\partial \dot{W}} = U'(-\dot{W}) e^{-\rho t} \cdot (-1) = -U'(c) e^{-\rho t}.$$

Setting this equal to a constant and differentiating with respect to t gives

$$\frac{d}{dt} [U'(c) e^{-\rho t}] = 0 \quad \Longleftrightarrow \quad U''(c) \dot{c} e^{-\rho t} - \rho U'(c) e^{-\rho t} = 0,$$

which yields the **Euler equation for consumption**:

$$\boxed{\frac{\dot{c}}{c} = \frac{U'(c)}{c U''(c)} \cdot \rho = -\sigma(c) \cdot \rho,}$$

where $\sigma(c) := -U'(c)/[c U''(c)] > 0$ is the intertemporal elasticity of substitution. Since $\sigma(c) > 0$ and $\rho > 0$, we conclude that $\dot{c} < 0$: the consumer optimally eats more cake today and less tomorrow, at a rate dictated by the discount rate and the curvature of U .

Special case (CRRA utility): if $U(c) = c^{1-\theta}/(1-\theta)$ with $\theta > 0$, then $\sigma(c) = 1/\theta$ is constant, and the Euler equation integrates to

$$c(t) = c(0) e^{-\rho t / \theta}.$$

Imposing the resource constraint $\int_0^T c(t) dt = W_0$ determines the initial consumption:

$$c(0) = \frac{W_0 \rho / \theta}{1 - e^{-\rho T / \theta}}.$$

Example 7.4. (Ramsey-Cass-Koopmans model) Consider an economy in which the capital stock $K(t)$, consumption $c(t)$, and output $Y(t)$ evolve over time. Technology is given by $Y = f(K)$, with $f'(K) > 0$ and $f''(K) \leq 0$. The resource constraint is $\dot{K} = f(K) - c$, with $K(0) = K_0$ and $K(T) = K_T$ given. Society values consumption through a utility $U(c)$ with $U'(c) > 0$ and $U''(c) < 0$. The problem is

$$\max_{K(t)} \int_0^T U(c(t)) e^{-rt} dt = \int_0^T \underbrace{U(f(K) - \dot{K})}_{= L} e^{-rt} dt,$$

where $r > 0$ is the discount rate. Applying Euler-Lagrange with state K and velocity $\dot{K}$, $\frac{\partial L}{\partial K} - \frac{d}{dt} \left(\frac{\partial L}{\partial \dot{K}} \right) = 0$, we compute

$$\frac{\partial L}{\partial K} = e^{-rt} U'(c) f'(K), \quad \frac{\partial L}{\partial \dot{K}} = -e^{-rt} U'(c),$$

and, using $\dot{c} = f'(K)\dot{K} - \ddot{K}$,

$$\frac{d}{dt}(-e^{-rt} U'(c)) = e^{-rt} [r U'(c) - U''(c) \dot{c}].$$

Substituting and simplifying yields

$$U'(c)[f'(K) - r] + U''(c)[f'(K)\dot{K} - \ddot{K}] = 0,$$

which is equivalent (exercise) to the **Keynes-Ramsey rule**

$$\frac{\dot{c}}{c} = -\frac{U'(c)}{c U''(c)} [f'(K) - r].$$

In particular, $\dot{c}/c > 0 \iff f'(K) > r$. Defining the intertemporal elasticity of substitution $\sigma(c) := -U'(c)/[c U''(c)] > 0$, we obtain the compact form

$$\boxed{\frac{\dot{c}}{c} = \sigma(c) [f'(K) - r].}$$

7.4 Transversality conditions

So far we have assumed that both endpoints (x_1, A) and (x_2, B) were fixed. When one endpoint is **free**, the Euler-Lagrange equation alone is not enough to pin down the solution — additional boundary conditions, called **transversality conditions**, are required.

Consider the problem

$$\max_y V = \int_0^T F(t, y, y') dt, \quad y(0) = A,$$

with T and $y(T) = y_T$ possibly free. Let $y^*(t)$ be the extremizing trajectory. Consider neighborhoods of the form

$$y(t) = y^*(t) + \delta h(t), \quad T = T^* + \delta T,$$

so that the variation of the terminal value is $\delta y = \delta h + \dot{y}^* \cdot \delta T$ (see exercise below).

The variation of the functional, assuming $\partial F / \partial t = 0$ in the explicit term, is

$$\delta V = \int_0^T \left[\frac{\partial F}{\partial y} - \frac{d}{dt} \left(\frac{\partial F}{\partial y'} \right) \right] \delta h dt + \left[\frac{\partial F}{\partial y'} \right]_T \delta y + \left[F - y' \frac{\partial F}{\partial y'} \right]_T \delta T.$$

For $\delta V = 0$, the following must hold simultaneously:

$$1. \text{ Euler-Lagrange: } \frac{\partial F}{\partial y} - \frac{d}{dt} \left(\frac{\partial F}{\partial y'} \right) = 0;$$

2. **Transversality conditions:**

$$\left[\frac{\partial F}{\partial y'} \right]_T \delta y = 0, \quad \left[F - y' \frac{\partial F}{\partial y'} \right]_T \delta T = 0.$$

Example 7.5. (Decomposition of δy) Let $y(t) = y^*(t) + \delta h(t)$ and $T = T^* + \delta T$. By Taylor expansion around T^* :

$$\begin{aligned} \delta y &:= y(T) - y^*(T^*) \approx y(T^*) + y'(T^*)(T - T^*) - y^*(T^*) \\ &= (y - y^*)(T^*) + y'(T^*) \delta T \\ &= \delta h(T^*) + y'(T^*) \delta T. \end{aligned}$$

Taking $T \rightarrow T^*$,

$$\delta y = \delta h + y' \cdot \delta T.$$

Boundary configurations

The transversality conditions take specific forms depending on the geometry of the terminal boundary:

- (i) **Vertical terminal line** (T^* given, $y(T^*)$ free): we have $\delta T = 0$ and $\delta y \neq 0$, so that

$$\left. \frac{\partial F}{\partial y'} \right|_{t=T^*} = 0.$$

- (ii) **Horizontal terminal line** (T free, y_T given): we have $\delta T \neq 0$ and $\delta y = 0$, so that

$$\left[F - y' \frac{\partial F}{\partial y'} \right]_{t=T} = 0.$$

- (iii) **Terminal curve** $y_T = \phi(T)$: in this case $\delta y = \phi'(T) \delta T$, and combining both terms yields

$$\left[F - (y' - \phi'(T)) \frac{\partial F}{\partial y'} \right]_{t=T} = 0.$$

7.5 Infinite horizon

In many economic problems, we take $T \rightarrow \infty$. The transversality condition

$$\left[F - y' \frac{\partial F}{\partial y'} \right]_{t \rightarrow \infty} \Delta T + \left[\frac{\partial F}{\partial y'} \right]_{t \rightarrow \infty} \Delta y_T = 0$$

splits into two cases:

- (i) If $\lim_{t \rightarrow \infty} y(t) = y_\infty$ is given, then $\Delta y_T = 0$ and

$$\lim_{t \rightarrow \infty} \left(F - y' \frac{\partial F}{\partial y'} \right) = 0.$$

- (ii) If y_∞ is free, then additionally

$$\lim_{t \rightarrow \infty} \frac{\partial F}{\partial y'} = 0.$$

Example 7.6. (*Ramsey-Cass-Koopmans with infinite horizon*) For

$$F = e^{-rt} U(f(K) - \dot{K})$$

with $c = f(K) - \dot{K}$, we have:

- Case (i): $\lim_{t \rightarrow \infty} e^{-rt} [U(c) + \dot{K} U'(c)] = 0$;
- Case (ii): $\lim_{t \rightarrow \infty} e^{-rt} U'(c) = 0$.

The latter is the well-known transversality condition of the optimal growth model: the discounted marginal utility of terminal consumption must tend to zero.

8 The Ramsey-Cass-Koopmans model

The Ramsey-Cass-Koopmans model is the *benchmark* of growth macroeconomics with microfoundations. Originally developed by Frank Ramsey in 1928, and revisited independently by David Cass and Tjalling Koopmans in the 1960s, the model describes an economy in which a representative agent chooses the optimal trajectory of consumption and capital accumulation, maximizing intertemporal welfare. The canonical reference for this lecture is Acemoglu (2008), ch. 8 [1].

8.1 Economic environment

Consider a closed economy, without government, with a single good that can be consumed or accumulated as capital. Time is continuous and the horizon is infinite. The economy is inhabited by a representative household of constant size (normalized to one), which derives instantaneous utility $U(c)$ from per capita consumption $c(t)$, satisfying

$$U'(c) > 0, \quad U''(c) < 0, \quad \lim_{c \rightarrow 0^+} U'(c) = +\infty.$$

The first two conditions reflect positive and diminishing marginal utility; the third (Inada condition) ensures that consumption is strictly positive along the optimal trajectory.

Technology is given by a production function $Y = F(K, L)$ with constant returns to scale, positive and diminishing marginal returns, and satisfying the Inada conditions:

$$F_K > 0, \quad F_{KK} < 0, \quad \lim_{K \rightarrow 0} F_K = +\infty, \quad \lim_{K \rightarrow \infty} F_K = 0.$$

Normalizing $L = 1$, we write $f(k) := F(k, 1)$, with $f'(k) > 0$ and $f''(k) < 0$.

Capital evolves according to the resource constraint

$$\dot{k}(t) = f(k(t)) - c(t) - \delta k(t),$$

where $\delta \geq 0$ is the depreciation rate. For simplicity, in this course we take $\delta = 0$; the general case is analogous.

8.2 The consumer's problem

The representative household solves

$$\max_{c(\cdot)} \int_0^\infty U(c(t)) e^{-\rho t} dt$$

subject to

$$\dot{k}(t) = f(k(t)) - c(t), \quad k(0) = k_0 > 0, \quad \lim_{t \rightarrow \infty} k(t) \geq 0,$$

where $\rho > 0$ is the intertemporal discount rate. The condition $k(t) \geq 0$ in the limit prevents the household from ending up indebted at infinity (*no-Ponzi* condition).

Remark. The condition $\rho > 0$ is necessary for the functional to converge: without discounting, the integral of $U(c) \cdot 1$ over $[0, \infty)$ typically diverges for growth trajectories. Exponential discounting is what makes the problem well-posed.

8.3 Variational formulation

We eliminate c from the constraint using $c = f(k) - \dot{k}$:

$$\max_{k(\cdot)} \int_0^\infty \underbrace{U(f(k) - \dot{k}) e^{-\rho t}}_{= F(t, k, \dot{k})} dt.$$

The problem now has k as the only choice variable, and falls into the standard form of the calculus of variations, with $F(t, k, \dot{k}) = U(f(k) - \dot{k}) e^{-\rho t}$.

8.4 Derivation via Euler-Lagrange

We apply the Euler-Lagrange equation:

$$\frac{\partial F}{\partial k} - \frac{d}{dt} \left(\frac{\partial F}{\partial \dot{k}} \right) = 0.$$

Computing each term:

$$\frac{\partial F}{\partial k} = U'(c) f'(k) e^{-\rho t}, \quad \frac{\partial F}{\partial \dot{k}} = -U'(c) e^{-\rho t}.$$

The total derivative of the second term is

$$\frac{d}{dt} (-U'(c) e^{-\rho t}) = -U''(c) \dot{c} e^{-\rho t} + \rho U'(c) e^{-\rho t}.$$

Substituting into the Euler-Lagrange equation:

$$U'(c) f'(k) e^{-\rho t} - [-U''(c) \dot{c} e^{-\rho t} + \rho U'(c) e^{-\rho t}] = 0.$$

Dividing by $e^{-\rho t} > 0$ and rearranging,

$$U'(c) [f'(k) - \rho] + U''(c) \dot{c} = 0,$$

which, isolating $\dot{c}$, yields the **consumption Euler equation**:

Euler equation (Keynes-Ramsey)

$$\frac{\dot{c}}{c} = -\frac{U'(c)}{c U''(c)} [f'(k) - \rho] = \sigma(c) [f'(k) - \rho],$$

where $\sigma(c) := -U'(c)/[c U''(c)] > 0$ is the *intertemporal elasticity of substitution*.

Remark. The economic interpretation is direct: consumption grows over time if and only if the marginal product of capital exceeds the discount rate. When $f'(k) > \rho$, it pays to postpone consumption (save), since the return on saving outweighs impatience; when $f'(k) < \rho$, the household prefers to consume now.

8.5 Transversality condition

Since the horizon is infinite and $k(\infty)$ is free (the household chooses how much capital to leave at infinity), an additional condition is needed to close the problem. Applying the transversality condition for infinite horizon:

$$\lim_{t \rightarrow \infty} \frac{\partial F}{\partial k} = 0 \quad \Longleftrightarrow \quad \lim_{t \rightarrow \infty} U'(c(t)) e^{-\rho t} = 0.$$

An equivalent and more common form in the literature uses the shadow price (marginal value of capital):

$$\lim_{t \rightarrow \infty} e^{-\rho t} U'(c(t)) k(t) = 0.$$

Economically, this condition ensures that the present value of the terminal capital stock is zero: the household neither accumulates capital without bound only to never consume it, nor borrows indefinitely.

8.6 Dynamic system and steady state

Combining the Euler equation with the resource constraint, we obtain the autonomous two-dimensional system

$$\begin{cases} \dot{c} = \sigma(c) c [f'(k) - \rho], \\ \dot{k} = f(k) - c. \end{cases}$$

The steady state (k^*, c^*) is characterized by $\dot{c} = \dot{k} = 0$:

$$\boxed{f'(k^*) = \rho, \quad c^* = f(k^*)}.$$

This is the **modified golden rule**: in steady state, the marginal product of capital equals the discount rate. Compare with the classical *golden rule* (Solow with s maximizing steady-state consumption), which would give $f'(k^{**}) = 0$ (in the absence of depreciation and population growth). Since $\rho > 0$, we have $k^* < k^{**}$: impatience leads agents to accumulate less capital than the technically maximum feasible.

8.7 Phase diagram

The system above has a unique interior equilibrium point, which is a **saddle point**. In the (k, c) plane:

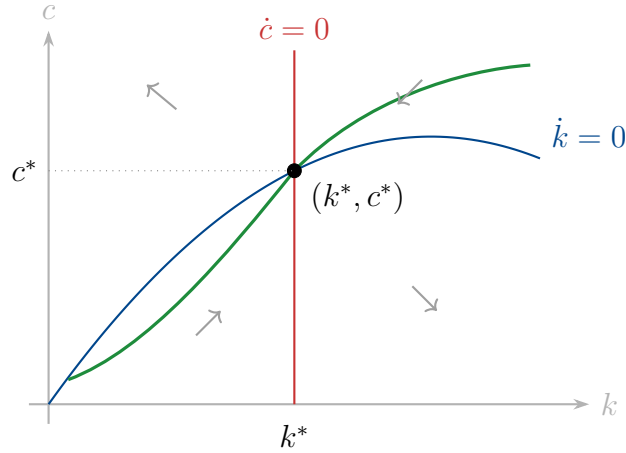

Figure 14: Phase diagram of the Ramsey-Cass-Koopmans model. The equilibrium (k^*, c^*) is a saddle point. The gray arrows show the direction of motion in each region; only the green trajectory (stable branch) converges to the equilibrium.

Of the infinitely many trajectories starting from $k(0) = k_0$, only one, along the **stable branch** of the saddle, converges to (k^*, c^*) . The others either drive capital to zero in finite time (with c exploding) or drive consumption to zero (with k growing unboundedly). The transversality condition selects precisely the trajectory that converges to the steady state.

8.8 CRRA case

When utility is of the CRRA type (*constant relative risk aversion*),

$$U(c) = \frac{c^{1-\theta} - 1}{1-\theta}, \quad \theta > 0, \theta \neq 1,$$

(and $U(c) = \ln c$ for $\theta = 1$), the elasticity $\sigma(c) = 1/\theta$ is constant. The Euler equation simplifies to

$$\frac{\dot{c}}{c} = \frac{1}{\theta} [f'(k) - \rho].$$

This will be the form most used in subsequent lectures, as it allows closed-form analytical solutions in several models.

9 Endogenous growth: the AK model

The Ramsey-Cass-Koopmans model predicts convergence to the steady state: in the long run, per capita income growth is zero (unless *exogenous* technical progress is introduced). This implication is uncomfortable, since the data show sustained per capita income growth in developed economies for over a century. The theory of **endogenous growth**, developed in the 1980s and 1990s, seeks to explain this growth from mechanisms internal to the model, without appealing to exogenous technical progress. In this lecture, we present the AK model, the simplest and most transparent version of this family. The main reference is Acemoglu (2008), ch. 11 [1].

9.1 The central idea

In the Ramsey model, the production function $f(k)$ satisfies the Inada conditions, in particular $\lim_{k \rightarrow \infty} f'(k) = 0$. This is what generates *diminishing returns*: as k grows, the marginal product falls, discouraging further accumulation. Eventually, $f'(k^*) = \rho$ and growth ceases.

The AK model breaks this dynamic by assuming a **linear** production function in capital:

$$f(k) = Ak, \quad A > 0.$$

Here, the marginal product $f'(k) = A$ is constant, regardless of how large k becomes. There are no diminishing returns, and capital accumulation can sustain growth indefinitely.

Remark. The function $f(k) = Ak$ admits several interpretations. One reading is that k includes not only physical capital but also *human capital* and other forms of reproducible capital, so that, in the aggregate, there is no fixed factor (such as raw labor) generating diminishing returns. Another reading, due to Romer (1986), is that there exist capital externalities (learning, spillovers) that offset private diminishing returns. In all interpretations, the point is that the accumulable factor has constant marginal product in the aggregate.

9.2 The problem

The consumer's problem is identical to Ramsey's, except for the production function:

$$\max_{c(\cdot)} \int_0^\infty U(c) e^{-\rho t} dt \quad \text{s.t.} \quad \dot{k} = Ak - c, \quad k(0) = k_0, \quad \lim_{t \rightarrow \infty} k(t) \geq 0.$$

We assume CRRA utility, $U(c) = c^{1-\theta}/(1-\theta)$, with $\theta > 0$, to obtain explicit solutions.

9.3 Derivation via Euler-Lagrange

Eliminating $c = Ak - \dot{k}$, the functional to maximize is

$$\int_0^\infty \frac{(Ak - \dot{k})^{1-\theta}}{1-\theta} e^{-\rho t} dt.$$

Defining $F(t, k, \dot{k}) = \frac{(Ak - \dot{k})^{1-\theta}}{1-\theta} e^{-\rho t}$ and applying Euler-Lagrange,

$$\frac{\partial F}{\partial k} - \frac{d}{dt} \left(\frac{\partial F}{\partial \dot{k}} \right) = 0,$$

we obtain, via calculation identical to Ramsey's with $f'(k) = A$:

Euler equation in AK

$$\frac{\dot{c}}{c} = \frac{1}{\theta}(A - \rho) =: g.$$

The novelty is that, since A is a *constant*, the growth rate of consumption is also constant over time. There is no transition dynamics: the economy already starts on its long-run growth rate.

Remark. For the problem to be well-posed, we require $A > \rho$ (so that $g > 0$ and there is growth) and also $A - \rho < \theta A$, equivalently $\rho > (1 - \theta)A$, to ensure convergence of the functional. Under logarithmic utility ($\theta = 1$), it suffices that $\rho > 0$.

9.4 Equilibrium trajectory

Solving the Euler equation,

$$c(t) = c(0) e^{gt}, \quad g = \frac{A - \rho}{\theta}.$$

Substituting into the resource constraint $\dot{k} = Ak - c$, we obtain the non-homogeneous linear ODE

$$\dot{k} - Ak = -c(0) e^{gt}.$$

The general solution is $k(t) = \alpha e^{At} + \beta e^{gt}$ for appropriate constants α, β . Imposing $k(0) = k_0$ and the transversality condition

$$\lim_{t \rightarrow \infty} e^{-\rho t} U'(c(t)) k(t) = \lim_{t \rightarrow \infty} e^{-\rho t} c(t)^{-\theta} k(t) = 0,$$

the explosive term e^{At} is eliminated, resulting in

$$k(t) = k_0 e^{gt}, \quad c(t) = c(0) e^{gt},$$

with $c(0)$ determined by the initial constraint. Indeed, imposing $\dot{k}(0) = Ak_0 - c(0) = g k_0$, we obtain

$$c(0) = (A - g) k_0 = \left(A - \frac{A - \rho}{\theta} \right) k_0 = \frac{(\theta - 1)A + \rho}{\theta} k_0.$$

Therefore, the entire economy grows at the constant rate g :

$$\frac{\dot{c}}{c} = \frac{\dot{k}}{k} = \frac{\dot{y}}{y} = g = \frac{A - \rho}{\theta}.$$

9.5 Implications

The AK model has several implications that contrast sharply with Ramsey:

1. **Absence of transitional dynamics.** The economy starts directly on its balanced growth path; there is no convergence to a steady state because there is no steady state (in the sense of constant k).

2. **No convergence across economies.** Two economies with the same parameters (A, ρ, θ) but different initial conditions grow at the same rate g , maintaining their relative income gap forever. This contrasts with Ramsey, where economies converge to the same k^* .
3. **Growth depends on structural parameters.** Policies that affect A (total productivity), ρ (impatience), or θ (intertemporal risk aversion) *permanently* affect the growth rate, not merely the level.
4. **Growth is endogenous.** There is no exogenous technical progress; growth emerges from the continuous accumulation of the reproducible factor k .

9.6 Limitations and extensions

The AK model is deliberately stylized. Its main limitations are:

1. The linearity $f(k) = Ak$ is a strong hypothesis with weak microeconomic justification. It is not obvious why aggregate capital would have constant marginal product;
2. Empirically, poor and rich economies do *not* grow at the same rate indefinitely; there is evidence of conditional convergence, which the pure AK model does not predict;
3. There is no role for innovation, R&D, or any microeconomic process that generates growth.

These limitations motivated extensions such as:

- **Romer (1986):** private diminishing returns, but positive externalities of aggregate capital, generating constant returns in the aggregate;
- **Lucas (1988), the Uzawa-Lucas model:** two reproducible factors, physical capital k and human capital h , with endogenous accumulation of h via time spent in education (the focus of the next lecture);
- **Romer (1990):** varieties of intermediate goods created by R&D, with monopolistic competition and increasing returns derived from the non-rivalry of knowledge.

All these extensions preserve the central idea: for sustained endogenous growth to arise, some accumulable factor must have a marginal product that does not tend to zero.
